HAKE (HAK)*(Merluccius australis)*

Tiikati

**1. FISHERY SUMMARY****1.1 Commercial fisheries**

Hake was introduced into the Quota Management System on 1 October 1986. Hake are widely distributed throughout the middle depths of the New Zealand EEZ, mostly south of 40° S. Adults are mainly distributed from 250–800 m, but some have been found as deep as 1200 m, while juveniles (0+) are found in inshore regions shallower than 250 m. Hake are taken mainly by large trawlers, often as bycatch in hoki target fisheries, although hake target fisheries do exist.

The largest fishery has been off the west coast of the South Island (HAK 7) with the highest catch (17 000 t) recorded in 1977, immediately before the establishment of the EEZ. The TACC for HAK 7 is the largest, at 5 064 t out of a total for the EEZ of 10 575 t. The WCSI hake fishery has generally consisted of bycatch in the much larger hoki fishery, but it has undergone a number of changes over time (Devine 2009). These include changes to the TACCs of both hake and hoki, and also changes in fishing practices such as gear used, tow duration, and strategies to limit hake bycatch. In some years there has been a hake target fishery in September after the peak of the hoki fishery is over; more than 2 000 t of hake were taken in this target fishery during September 1993 (Ballara 2015). High bycatch levels of hake early in the fishing season have also occurred in some years (Ballara 2015). From 1 October 2005 the TACC for HAK 7 was increased to 7 700 t within an overall TAC of 7 777 t. This new catch limit was set equal to average annual catches over the previous 12 years. HAK 7 landings have been relatively low since 2007–08, however, and were less than 3 000 t in 2007–08, 2009–10, and 2015–16.

On the Chatham Rise and in the Sub-Antarctic, hake have been caught mainly as bycatch by trawlers targeting hoki (Devine 2009). However, significant targeting for hake has occurred in both areas, particularly in Statistical Area 404 (HAK 4), and around the Norwegian Hole between the Snares and Auckland Islands in the Sub-Antarctic. Increases in TACCs from 2 610 t to 3 632 t in HAK 1 and from 1 000 t to 3 500 t in HAK 4 from the 1991–92 fishing year allowed the fleet to increase their reported landings of hake from these fish stocks. Reported catches rose over a number of years to the levels of the new TACCs in both HAK 1 and HAK 4. In HAK 1, annual catches remained relatively steady (generally between 3 000 and 4 000 t) up to 2004–05, but were generally less than 3 000 t from 2005–06 until 2009–10, and generally less than 2 000 t since then. Landings from HAK 4 declined erratically from over 3 000 t in 1998–99 to a low of 161 t in 2011–12. From 2004–05, the TACC for HAK 4 was reduced from 35 00 t to 18 00 t. Annual landings have been markedly lower than the new TACC since then, and lower than 300 t in all but one year since 2009–10.

HAKE (HAK)

An unusually large aggregation of possibly mature or maturing hake was fished on the western Chatham Rise, west of the Mernoo Bank (HAK 1) in October 2004. Over a four week period, about 2 000 t of hake were caught from that area. In previous years, catches from this area have typically been between 100–800 t. These unusually high catches resulted in the TACC for HAK 1 being over-caught during the 2004–05 fishing year (4 795 t against a TACC of 3 701 t) and a substantial increase in the landings (more than 3 700 t) associated with the Chatham Rise. Fishing on aggregated schools in the same area also occurred during October–November 2008 and 2010 (Ballara 2015).

Reported catches from 1975 to 1987–88 are shown in Table 1. Reported landings for each Fishstock since 1983–84 and TACCs since 1986–87 are shown in Table 2. Figure 1 shows the historical landings and TACC values for the main hake stocks.

Table 1: Reported hake catches (t) from 1975 to 1987–88. Data from 1975 to 1983 from MAF; data from 1983–84 to 1985–86 from FSU; data from 1986–87 to 1987–88 from QMS.

¹ FSU data

Figure 1: Reported commercial landings and TACC for the three main HAK stocks. From top: HAK 1 (Sub-Antarctic and part of Chatham Rise), HAK 4 (eastern Chatham Rise), and HAK 7 (Challenger).

1.2 Recreational fisheries

The recreational fishery for hake is negligible.

1.3 Customary non-commercial fisheries

The amount of hake caught by Maori is not known but is believed to be negligible.

HAKE (HAK)

1.4 Illegal catch

In late 2001, a small number of fishers admitted misreporting of hake catches between areas, pleading guilty to charges of making false or misleading entries in their catch returns. As a result, the reported catches of hake in each area were reviewed in 2002 and suspect records identified. Dunn (2003) provided revised estimates of the total landings by stock, estimating that the level of hake over-reporting on the Chatham Rise (and hence under-reporting on the west coast South Island) was between 16 and 23% (700–1 000 t annually) of landings between 1994–95 and 2000–01, mainly in June, July, and September. Probable levels of area misreporting prior to 1994–95 and between the west coast South Island and Sub-Antarctic were estimated as small (Dunn 2003). There is no evidence of similar area misreporting since 2001–02 (Devine 2009, Ballara 2015).

In earlier years, before the introduction of higher TACCs in 1991–92, there is some evidence to suggest that catches of hake were not always fully reported. Comparison of catches from vessels carrying observers with those not carrying observers, particularly in HAK 7 from 1988–89 to 1990–91, suggested that actual catches were probably considerably higher than reported catches. For these years, the ratio of hake to hoki in the catch of vessels carrying observers was significantly higher than in the catch of vessels not carrying observers (Colman & Vignaux 1992). The actual hake catch in HAK 7 for these years was estimated by multiplying the total hoki catch (which was assumed to be correctly reported by vessels both with and without observers) by the ratio of hake to hoki in the catch of vessels carrying observers. Reported and estimated catches for 1988–89 were respectively 6 835 t and 8 696 t; for 1989–90, 4 903 t reported and 8 741 t estimated; and for 1990–91, 6 189 t reported and 8 246 t estimated. More recently, the level of such misreporting has not been estimated and is not known. No such corrections have been applied to either the HAK 1 or HAK 4 fishery.

For the purposes of stock assessment, the Chatham Rise stock was considered to include the whole of the Chatham Rise (including the western end currently forming part of the HAK 1 management area). Therefore, catches from this area were subtracted from the Sub-Antarctic stock and added to the Chatham Rise stock. The revised landings for 1974–75 to 2014–15 are given in Table 3.

Table 3: Revised landings from fishing years 1974–75 to 2014–15 (t) for the west coast South Island, Sub-Antarctic, and Chatham Rise stocks.

2014–15	5 966	1 630	348

1. West coast South Island revised estimates for 1989–90 and 1990–91 are taken from Colman & Vignaux (1992) who corrected for underreporting in 1989–90 and 1990–91, and not from Dunn (2003) who ignored such underreporting.

1.5 Other sources of mortality

There is likely to be some mortality associated with escapement from trawl nets, but the level is not known and is assumed to be negligible.

2. BIOLOGY

The New Zealand hake reach a maximum age of at least 25 years. Males, which rarely exceed 100 cm total length (TL), do not grow as large as females, which can grow to 120 cm TL or more. Horn (1997) validated the use of otoliths to age hake, and produced von Bertalanffy growth parameters. Growth parameters were updated by Horn (2008) using both the von Bertalanffy and Schnute growth models. The Schnute model was found to better fit the data. Chatham Rise hake reach 50% maturity at about 5.5 years for males and 7 years for females, Sub-Antarctic hake at about 6 years for males and 6.5 years for females, and WCSI hake at about 4.5 years for males and 5 years for females (Horn & Francis 2010, Horn 2013a.).

Estimates of natural mortality (M) and the associated methodology are given in Dunn et al (2000); M is estimated as 0.18 y^{-1} for females and 0.20 y^{-1} for males. Colman et al (1991) previously estimated M as 0.20 y^{-1} for females and 0.22 y^{-1} for males from the maximum age (i.e., the maximum ages at which 1% of the population survives in an unexploited stock were estimated at 23 years for females and 21 years for males). Recent assessment models for all hake stocks have either assumed a constant M (0.19 yr^{-1} for both sexes), estimated a constant M , or have estimated age-dependent ogives for M (because true M is likely to vary with age).

Data collected by observers on commercial trawlers and data from trawl surveys suggest that there are at least three main spawning areas for hake (Colman 1998). The best known area is off the west coast of the South Island, where the season can extend from June to October, usually with a peak in September. Spawning also occurs to the west of the Chatham Islands during a prolonged period from at least September to January. Spawning on the Campbell Plateau, primarily to the north-east of the Auckland Islands, occurs from September to February with a peak in September–October. Spawning fish have been recorded occasionally on the Puysegur Bank, with a seasonality that appears similar to that on the Campbell Plateau (Colman 1998).

An aggregation of medium size hake fished on the western Chatham Rise in October 2004 may have comprised either spawning or pre-spawning fish. Fishing on aggregated schools in the same area also occurred during October–November 2008 and 2010. Also, the trawl survey took high catches of young, mature fish in this area in January 2009. It is possible that young, mature hake spawn on the western Chatham Rise and slowly move east, towards the main spawning area, as they age.

Juvenile hake have been taken in coastal waters on both sides of the South Island and on the Campbell Plateau. They reach a length of about 15–20 cm total length at one year old, and about 35 cm total length at 2 years (Colman 1998).

Dunn et al (2010) found that the diet of hake on the Chatham Rise was dominated by teleost fishes, in particular Macrouridae. Macrouridae accounted for 44% of the prey weight and consisted of at least six species, of which javelinfish, *Lepidorhynchus denticulatus*, was most frequently identified. Hoki were less frequent prey, but being relatively large accounted for 37% of prey by weight. Squid were found

HAKE (HAK)

in 7% of the stomachs, and accounted for 5% of the prey by weight. Crustacean prey were predominantly natant decapods, with pasiphaeid prawns, occurring in 19% of the stomachs.

The biological parameters relevant to the stock assessments are given in Table 4.

Table 4: Estimates of biological parameters.

Parameter					Estimate	Source							
<u>1. Natural mortality</u>													
	Males	$M = 0.20$				(Dunn et al 2000)							
	Females	$M = 0.18$				(Dunn et al 2000)							
	Both sexes	$M = 0.19$				(Horn & Francis 2010)							
<u>2. Weight = $a \cdot (\text{length})^b$ (Weight in t, length in cm)</u>													
Sub-Antarctic	Males	$a = 2.13 \times 10^{-9}$	$b = 3.281$	(Horn 2013a)									
	Females	$a = 1.83 \times 10^{-9}$	$b = 3.314$	(Horn 2013a)									
	Both sexes	$a = 1.95 \times 10^{-9}$	$b = 3.301$	(Horn 2013a)									
Chatham Rise	Males	$a = 2.56 \times 10^{-9}$	$b = 3.228$	(Horn 2013a)									
	Females	$a = 1.88 \times 10^{-9}$	$b = 3.305$	(Horn 2013a)									
	Both sexes	$a = 2.00 \times 10^{-9}$	$b = 3.288$	(Horn 2013a)									
WCSI	Males	$a = 2.85 \times 10^{-9}$	$b = 3.209$	(Horn 2013a)									
	Females	$a = 1.94 \times 10^{-9}$	$b = 3.307$	(Horn 2013a)									
	Both sexes	$a = 2.01 \times 10^{-9}$	$b = 3.294$	(Horn 2013a)									
<u>3. von Bertalanffy growth parameters</u>													
Sub-Antarctic	Males	$k = 0.295$	$t_0 = 0.06$	$L_\infty = 88.8$	(Horn 2008)								
	Females	$k = 0.220$	$t_0 = 0.01$	$L_\infty = 107.3$	(Horn 2008)

3. STOCKS AND AREAS

There are three main hake spawning areas; off the west coast of the South Island, on the Chatham Rise and on the Campbell Plateau. Juvenile hake are found in all three areas. There are differences in size frequencies of hake between the west coast and other areas, and differences in growth parameters between all three areas (Horn 1997). There is good evidence, therefore, to suggest that at least three separate stocks may exist in the EEZ.

Analysis of morphometric data (Colman unpublished data) shows little difference between hake from the Chatham Rise and hake from the east coast of the North Island, but shows highly significant differences between these fish and those from the Sub-Antarctic, Puysegur, and on the west coast. No studies have been done on morphometric differences of hake across the Chatham Rise. The Puysegur

fish are most similar to those from the west coast South Island, although, depending on which variables are used, they cannot always be distinguished from the Sub-Antarctic hake. Hence, the stock affinity of hake from this area is uncertain.

Present management divides the fishery into three Fishstocks: (a) the Challenger FMA (HAK 7), (b) the Chatham Rise FMA (HAK 4) and (c), the remainder of the EEZ comprising the Auckland, Central, Southeast (Coast), Southland and Sub-Antarctic FMAs (HAK 1). An administrative fish stock (with no recorded landings) exists for the Kermadec FMA (HAK 10).

4. STOCK ASSESSMENT

The stock assessments reported here were completed in 2018 for the Sub-Antarctic stock and in 2017 for the Chatham Rise and west coast South Island stocks (Horn 2017). In stock assessment modelling, the Chatham stock was considered to include the whole of the Chatham Rise (including the western end currently forming part of the HAK 1 management area). The Sub-Antarctic stock was considered to comprise the Southland and Sub-Antarctic management areas. Although fisheries management areas around the North Island are also included in HAK 1, few hake are caught in these areas.

4.1 HAK 1 (Sub-Antarctic stock)

The 2018 stock assessment was carried out with data up to the end of the 2016–17 fishing year, implemented as a Bayesian model using the general-purpose stock assessment program CASAL v2.30 (Bull et al 2012). The assessment used research time series of abundance indices (trawl surveys of the Sub-Antarctic from 1991 to 2016), catch-at-age from the trawl surveys and the commercial fishery since 1990–91, and estimates of biological parameters. A trawl fishery CPUE series was used in a sensitivity run.

4.1.1 Model structure

The model had a single area, and was single-sex and age-structured, partitioned into age groups 1–30 with the last age group considered a plus group. Maturity was fixed and estimated outside of the model.

The model was initialised assuming an equilibrium age structure at an unfished equilibrium biomass (B_0), i.e., with constant recruitment set equal to the mean of the recruitments over the period 1974–2014. The selectivity for the fishery was assumed to be logistic, and the selectivities were domed (double normal) for each of the November–December and April–May trawl survey series (with the September 1992 survey assumed to have a selectivity equal to the April–May series). Selectivities were assumed constant across all years in the fishery and the surveys, and hence there was no allowance for possible annual changes in selectivity. Growth was assumed to be constant and fixed. Natural mortality was estimated as a constant. Year class strengths were estimated.

Model parameters were estimated using Bayesian estimation implemented using the CASAL software (Bull et al 2012). For final model runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm.

4.1.2 Fixed biological parameters and observations

There were five main data sources: the catch history; research trawl survey biomass indices from November–December 1992–2017, April–May 1992–98, and September 1992; catch-at-age estimates from the research surveys; catch-at-age estimates from the commercial fishery 1990–2017; and a commercial CPUE biomass index 1991–2017 (sensitivity run only).

Catch history

In order to more closely align with the seasons of the fishery, the model year was set as September to August, rather than the fishing year (October to September). The catch history was modified accordingly (Table 5). The catch history includes the revised estimates of catch reported by Dunn (2003).

Table 5: Commercial catch history (t) for the Sub-Antarctic stock. Note that from 1990 totals by model year differ from those for fishing year (see Table 3) because the September catch has been shifted from the fishing year into the following model year. Model year landings from 2018 assume catch to be the same as the previous year.

Model year	Total	Model year	Total
1975	120	1997	1 915
1976	281	1998	2 958
1977	372	1999	2 854
1978	762	2000	3 108
1979	364	2001	2 820
1980	350	2002	2 444
1981	272	2003	2 777
1982	179	2004	3 223
1983	448	2005	2 592
1984	722	2006	2 541
1985	525	2007	1 711
1986	818	2008	2 329
1987	713	2009	2 446
1988	1 095	2010	1 927
1989	1 237	2011	1 319
1990	1 897	2012	1 900
1991	2 381	2013	1 859
1992	2 810	2014	1 800
1993	3 941	2015	1 600
1994	1 596	2016	1 464
1995	1 995	2017	1 033
1996	2 779	2018	1 033

Biological parameters

All biological parameters other than natural mortality rate M were estimated outside of the model. Estimated and assumed values for biological parameters used in the assessments are given in Table 4.

Growth was constant and followed the Schnute parameterisation. M was constant, and estimated with an informed prior (Table 6). A Beverton-Holt stock recruitment relationship was used with an assumed steepness h of 0.8. Year class strengths were estimated for the period 1974–2014, following the Haist parameterisation, with a lognormal prior. Ageing error was assumed (with C.V. = 0.08). All mature fish were assumed to spawn every year.

Table 6: The assumed priors for key distributions (when estimated) for the Sub-Antarctic stock assessment. The parameters are mean (in natural space) and CV for lognormal.

Parameter description	Distribution	Parameters		Bounds	
B_0	Uniform-log	–	–	5 000	600 000
Year class strengths	Lognormal (μ , cv)	1.0	1.1	0.01	100
Trawl survey q^1	Lognormal (μ , cv)	0.16	0.79	0.01	0.4
CPUE q	Uniform-log	–	–	1e-8	1e-3
Selectivities	Uniform	–	–	1	20–200 ²
M	Normal (μ , sd)	0.19	0.05	0.05	0.40

¹ Three trawl survey q values were estimated, but all had the same priors.

² A range of maximum values was used for the upper bound.

Research trawl surveys

The biomass estimates from the research trawl surveys are given in Table 7.

Table 7: Research survey indices (and associated CVs) for the Sub-Antarctic stock.

Fishing Year	Vessel	Nov–Dec series ¹		Apr–May series ²		Sep series ²

* Not used in the reported assessment.

Notes: (1) Series based on indices from 300–800 m core strata, including the 800–1000 m strata in Puysegur, but excluding Bounty Platform, (2) Series based on the biomass indices from 300–800 m core strata, excluding the 800–1000 m strata in Puysegur and the Bounty Platform. (3) Due to bad weather, the core survey strata were unable to be completed in 2017; biomass estimates were scaled-up using factors based on the proportion of hake biomass in those strata in previous surveys from 2000 to 2014. This introduced additional uncertainty into the 2017 biomass estimate (O'Driscoll et al., in prep.)

The priors for survey q s were estimated by assuming that q was the product of areal availability, vertical availability, and vulnerability. A simple simulation was conducted that estimated a distribution of possible values for the relativity constant by assuming that each of these factors was uniformly distributed. A prior was then determined by assuming that the resulting sampled distribution was lognormally distributed. Values assumed for the parameters were: areal availability (0.50–1.00), vertical availability (0.50–1.00), and vulnerability (0.01–0.50). The resulting (approximate lognormal) distribution had mean 0.16 and CV 0.79, with bounds assumed to be (0.01–0.40) (Table 6). Note that the values of survey relativity constants are dependent on the selectivity parameters, and the absolute catchability can be determined by the product of the selectivity by age and sex, and the relativity constant q . All trawl q s were estimated as free (not nuisance) parameters.

Biomass indices were fitted with lognormal likelihoods with assumed CVs set equal to the sampling CV. The CVs (for observations fitted with lognormal likelihoods) are assumed to have allowed for sampling error only. Additional variance, assumed to arise from differences between model simplifications and real world variation, was added to the sampling variance for all observations in all model runs. Process error of 0.2 was added to all survey biomass indices following the recommendation of Francis et al (2001). For the CPUE index, the process error CV was assumed to be 0.25.

Catch-at-age

Catch-at-age observations were available for each trawl survey of the Sub-Antarctic, and for the commercial fisheries from observer data. A plus group for all the catch-at-age data was set at 21 with the lowest age set at 3. Catch-at-age distributions were fitted assuming multinomial errors, with an effective sample size set following Francis (2011) (Table 8).

Table 8: Catch-at-age data for the Sub-Antarctic stock, giving the multinomial effective sample sizes assumed for each sample. The effective sample size is proportional to the weight given to the data in the model fit.

Fishing year	Nov-Dec	Apr-May	Research survey September	Commercial catch-at-age

4.1.3 Model estimation

In the base model, the main parameters estimated were: virgin (unfished, equilibrium) biomass (B_0), trawl-survey selectivity, fishery selectivity, natural mortality rate, and year class strengths (YCS) from 1974 to 2014.

A wide range of sensitivity models were run. Sensitivity models reported here were run to investigate the effect of estimating M as an age-dependent ogive while assuming a double normal selectivity for the fishery (to match the assumptions of the previous assessment) and alternative assumptions for the prior on year class strength. Additional sensitivity models not reported included one that used only data from the commercial fishery (CPUE series and catch-at-age).

The fits to the biomass indices were acceptable (Figure 2). Fits to the catch-at-age were generally good, although relatively strong recruitment from around 1992 apparent in the observer samples was not well fitted (Figure 3); this recruitment was not apparent in the research survey samples (Figure 4).

Figure 2: Fits of the base model for the Sub-Antarctic stock (solid lines) to the April-May (a) and November-December (d) research trawl biomass indices. Vertical lines indicate the 95% CI.

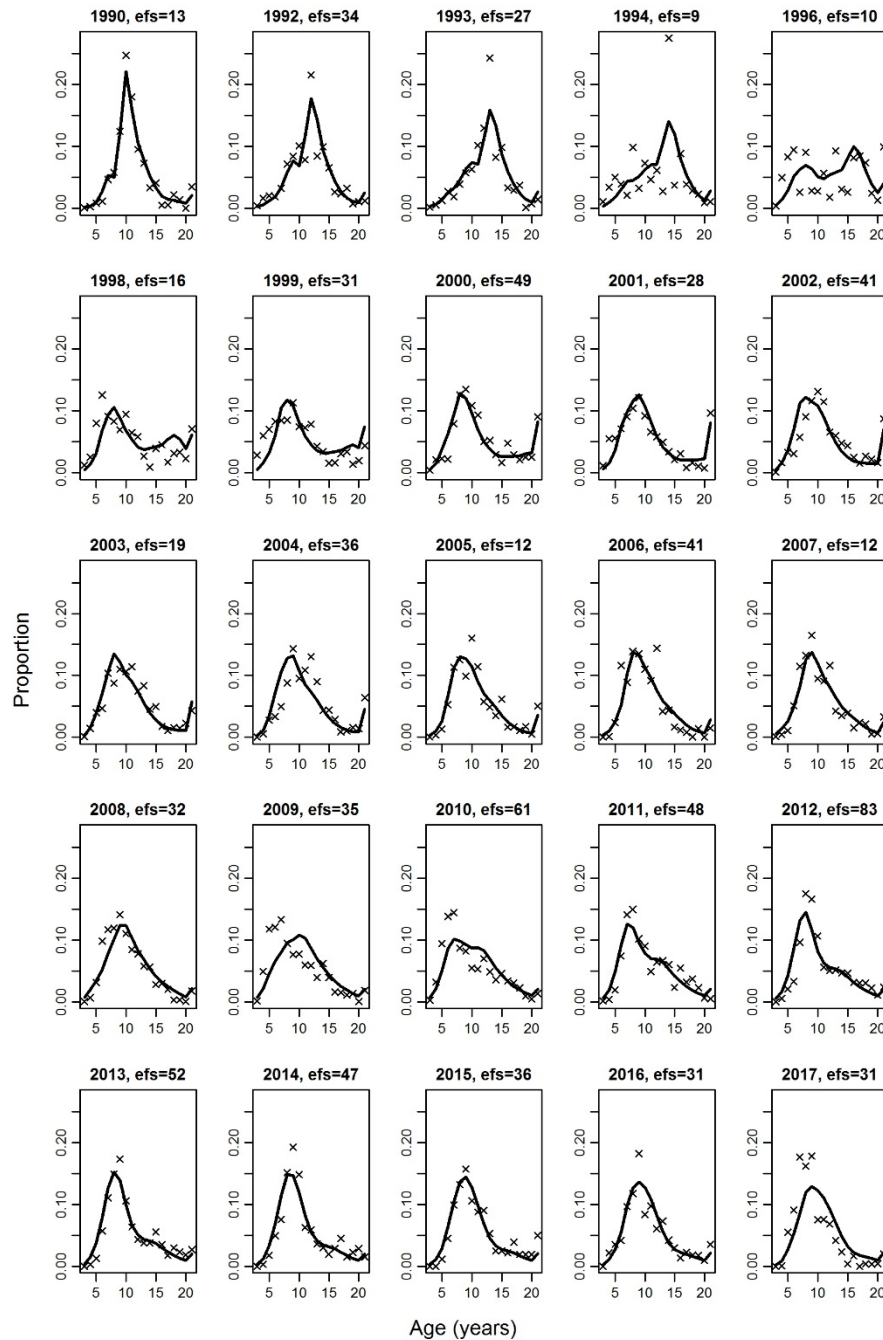

Figure 3: Model fit (solid lines) to the catch-at-age observations from the observer commercial fishery samples (x) for the base model run for the Sub-Antarctic stock. EFS, multinomial effective sample size.

Estimated selectivities for the surveys were not strongly domed (even though they were estimated using double-normal parameterisation). Hake were fully selected by the November-December survey at age 4.5, by the April-May and September surveys at age 15, and by the fishery at about age 10.

Year class strength estimates suggested that the Sub-Antarctic stock was characterised by a group of above average year class strengths in the late 1970s, a very strong year class in 1980, followed by a period of average to less than average recruitment through to 2014 (Figure 5).

The absolute catchability of the Sub-Antarctic trawl surveys was estimated to be extremely low (Figure 6). Although catchability was expected to be higher, hake are believed to be relatively more abundant over rough ground (that is likely to be avoided during a trawl survey), and it is known that hake tend to school off the bottom, particularly during their spring–summer spawning season, hence reducing their availability to the bottom trawl.

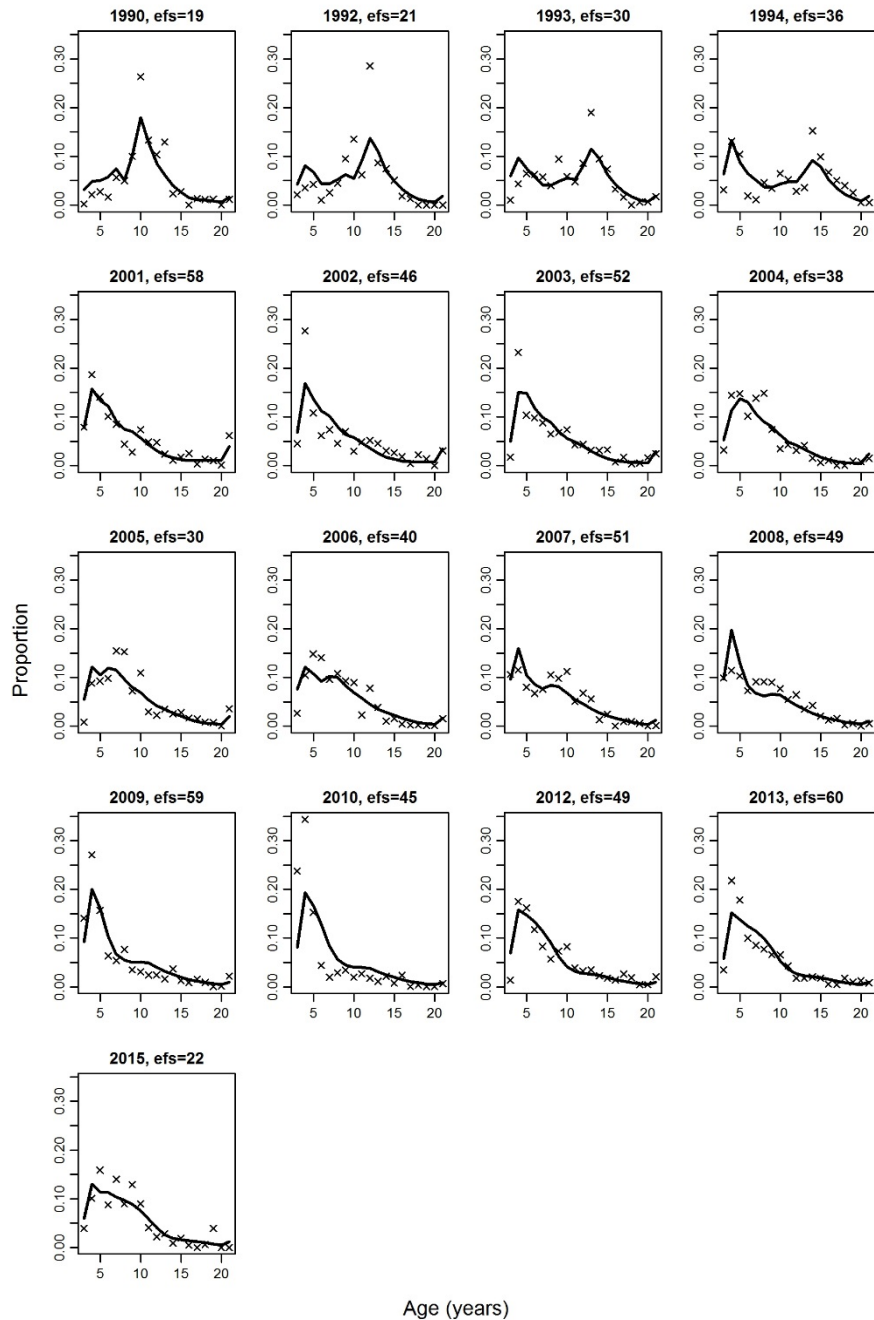

Figure 4: Model fit (solid lines) to the catch-at-age observations from the November-December research trawl survey samples (x) for the base model run for the Sub-Antarctic stock. EFS, multinomial effective sample size.

Biomass estimates for the stock appeared relatively healthy, with estimated current biomass from the base model at about 55% B_0 (Figure 7, Table 9). Annual exploitation rates (catch over vulnerable biomass) were low in all years as a consequence of the high estimated stock size relative to the level of catches (Figure 8).

A wide range of sensitivity runs was conducted, but in general these produced similar estimates of stock size and status. The 2018 assessment model was different to the previous (2014) model in assuming a logistic rather than domed selectivity for the fishery, and a constant rather than at-age natural mortality rate. However, the biomass estimates from the base model and previous model (run Previous) were similar (Table 9). The MPD model runs were found to be sensitive to the assumed prior on year class strengths (the CV, σ_R), but modifying σ_R to 0.7 made little difference to MCMC results (run Base 0.7). The sensitivity run using only commercial fishery data (run Commercial; CPUE and observer catch-at-age only) did not allow the observer catch-at-age to be better fitted, and was not considered plausible.

Figure 5: Estimated posterior distributions of year class strengths for the base case for the Sub-Antarctic stock. The dashed horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

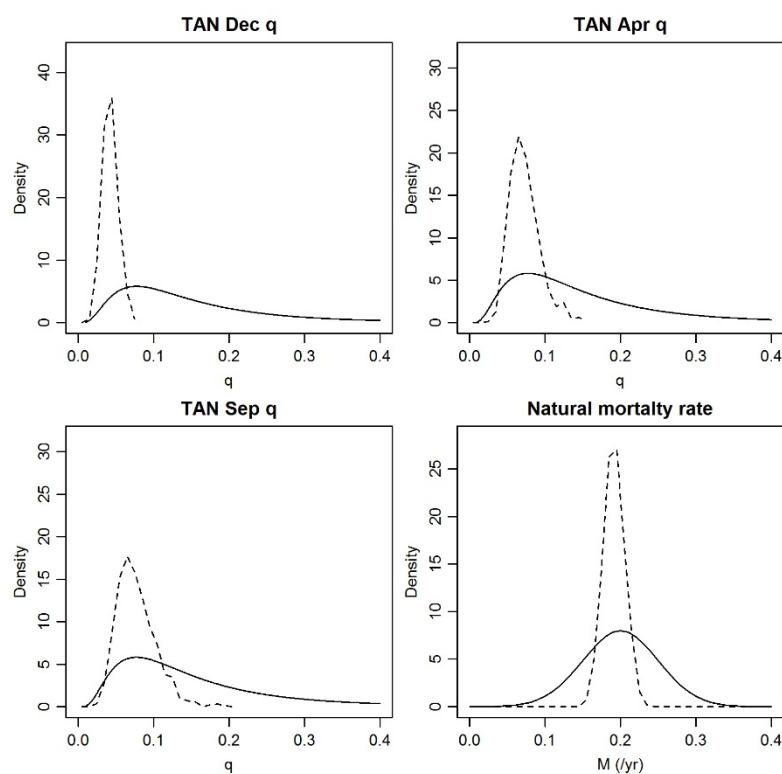

Figure 6: Estimated prior (solid lines) and posterior distributions (broken line) of catchability for the research trawl surveys, and natural mortality rate, for the base case for the Sub-Antarctic stock.

HAKE (HAK)

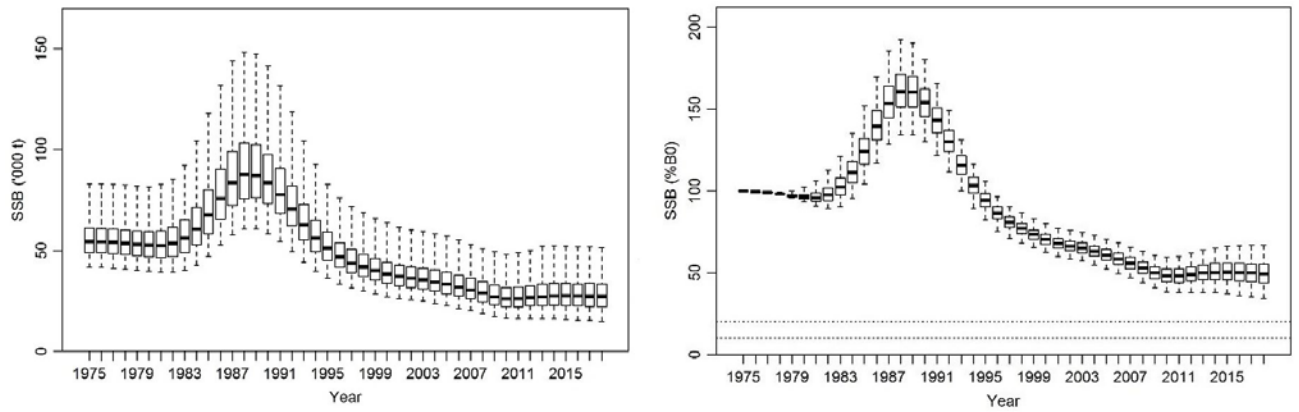

Figure 7: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for the Sub-Antarctic stock base case model for absolute biomass and biomass as a percentage of B_0 . The management target (40% B_0 , solid horizontal line) and soft limit (20% B_0 , dotted horizontal line) are shown on the right-hand panel.

Figure 8: Exploitation rates (catch over vulnerable biomass) for the Sub-Antarctic stock base case model. The horizontal broken line indicates the exploitation rate at 40% B_0 (U_{40} ; median derived from MCMC samples).

Table 9: Bayesian median (95% credible intervals) (MCMC) of B_0 , B_{2018} , B_{2018} as a percentage of B_0 , and the probability of B_{2018} being below the target (40% B_0), for the Sub-Antarctic base model and sensitivity runs.

Model run	B_0	B_{2018}	B_{2018} (% B_0)	$P(B_{2018} > 0.4 B_0)$
Base	54 600 (41 500–83 200)	27 200 (14 800–51 300)	49 (34–67)	0.11
Previous	54 400 (40 100–85 400)	31 700 (16 900–61 200)	57 (40–78)	0.03
Base 0.7	52 600 (41 700–80 100)	27 900 (16 100–52 100)	53 (38–70)	0.05

Projections

Five-year biomass projections were made for the Base model run assuming future catches in the Sub-Antarctic to be an average of the catch from the last three years (1366 t), or the TACC (3701 t). For each projection scenario, future recruitment variability was sampled from actual estimates between 1974 and 2012 (entire time series, where all year classes measured at least three times), or 2003 and 2012 (last ten years).

Table 10: HAK 1 Bayesian median and 95% credible intervals (in parentheses) of projected B_{2023} , B_{2023} as a percentage of B_0 , and B_{2023}/B_{2018} (%) for the model runs.

Model run	Catch	B_{2023}	B_{2023} (% B_0)	B_{2023}/B_{2018} (%)	$p(B_{2023} < 0.2 B_0)$	$p(B_{2023} < 0.1 B_0)$
Base 1974–2012	1 366	28 800 (14 500–59 500)	52 (33–81)	104 (76–154)	0	0
	3 701	21 000 (7 000–51 800)	38 (16–71)	76 (40–131)	0.05	0.01
Base 2003–2012	1 366	26 200 (13 300–53 200)	47 (30–72)	95 (73–130)	0	0
	3 701	18 400 (5 600–46 100)	33 (12–61)	67 (34–103)	0.12	0.01

At the current catch (1 366 t), SSB is predicted to remain stable over the next five years (Table 10). At a catch of the TACC (3 701 t), SSB is predicted to decrease. At the current catch, the estimated probability of SSB falling below the soft or hard limits is zero. At the TACC, the probability of the SSB dropping below the soft limit is 5% if large year classes such as those seen around 1980 are possible, and 12% if year class strength remains at recent levels.

4.2 HAK 4 (Chatham Rise stock)

The 2017 stock assessment was carried out with data up to the end of the 2015–16 fishing year. The assessment used research time series of abundance indices (trawl surveys of the Chatham Rise from 1992 to 2016), catch-at-age from the trawl survey series and the commercial fishery since 1990–91, a CPUE series from the eastern trawl fishery, and estimates of biological parameters.

4.2.1 Model structure

The base case model partitioned the Chatham Rise stock population into unsexed age groups 1–30 with the last age group considered a plus group. No CPUE was included, and a constant M was used. The models were initialised assuming an equilibrium age structure at an unfished equilibrium biomass (B_0), i.e., with constant recruitment set equal to the mean of the recruitments over the period 1975–2013. There were three double-normal selectivity-at-age ogives; east and west commercial fishing selectivities and a survey selectivity for the Chatham Rise January trawl survey series. Selectivities were assumed constant across all years in both fisheries and the survey, and hence there was no allowance for possible annual changes in selectivity. The age at full selectivity for the trawl survey series was strongly encouraged to be in the range 8 ± 2 years. This range was determined by visual examination of the at-age plots, and was implemented because unconstrained selectivity resulted in age at full selectivity being older than most of the fish caught in the survey series.

Five-year biomass projections were made assuming future catches on the Chatham Rise equal to the HAK 4 TACC of 1 800 t or the mean annual catch over the last six years (400 t). For the projections, estimated future recruitment variability was sampled from actual estimates between 1984 and 2013, a period including the full range of recruitment successes.

4.2.2 Fixed biological parameters and observations

Estimates and assumed values for biological parameters used in the assessments are given in Table 4. Variability in the Schnute age-length relationship was assumed to be lognormal with a constant CV of 0.1.

Catch-at-age observations were available for each survey on the Chatham Rise, and for commercial trawl fisheries on the eastern and western Rise in some years, from observer data. The catch histories assumed in all model runs (Table 11) include the revised estimates of catch reported by Dunn (2003). Resource survey abundance indices are given in Table 12.

4.2.3 Model estimation

Model parameters were derived using Bayesian estimation implemented using the general-purpose stock assessment program CASAL v2.30 (Bull et al 2012). For final runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm.

The error distributions assumed were multinomial for the proportions-at-age and lognormal for all other data. Biomass indices had assumed CVs set equal to the sampling CV, with additional process error of 0.15 estimated from an MPD run. A process error CV of 0.20 for the CPUE series was estimated following Francis (2011). The multinomial observation error effective sample sizes for the at-age data were adjusted using the reweighting procedure of Francis (2011). Ageing error was assumed to occur for the observed proportions-at-age data, by assuming a discrete normally distributed error with a CV of 0.08.

Table 11: Commercial catch history (t) by fishery (East and West) and total, for the Chatham Rise stock.

Model year	West	East	Total	Model year	West	East	Total
1975	80	111	191	1996	1 353	2 483	3 836

2016	<i>Tangaroa</i>	1 299	0.14

Year class strengths were assumed known (and equal to one) for years before 1975 and after 2013, where inadequate or no catch-at-age data were available. Otherwise year class strengths were estimated under the assumption that the estimates from the model should average one.

MCMCs were estimated using a burn-in length of 3×10^6 iterations, with every 5000th sample taken from the next 5×10^6 iterations (i.e., a final sample of length 1000 was taken from the Bayesian posterior).

4.2.4 Prior distributions and penalty functions

The assumed prior distributions used in the assessment are given in Table 13. The priors for B_0 and year class strengths were intended to be relatively uninformed, and had wide bounds. Priors for the trawl fishery selectivity parameters were assumed to be uniform. Priors for the trawl survey selectivity parameters were assumed to have a normal-by-stdev distribution, with a very tight distribution set for age at full selectivity, but an essentially uniform distribution for parameters aL and aR . The prior for the survey q was informative and was estimated using a simple simulation as described in Section 4.1.4

above. The prior for M was informative and assumed a normal distribution with a CV of 0.2 around a mean of 0.19.

Penalty functions were used a) to constrain the model so that any combination of parameters that resulted in a stock size that was so low that the historical catch could not have been taken was strongly penalised, b) to ensure that all estimated year class strengths averaged 1, and c) to smooth the year class strengths estimated over the period 1975 to 1983.

Table 13: The assumed priors for key distributions (when estimated) for the Chatham Rise stock assessment. The parameters are mean (in natural space) and CV for lognormal and normal priors, and mean (in natural space) and standard deviation for normal-by-stdev priors.

Parameter description	Distribution	Parameters		Bounds	
B_0	Uniform-log	–	–	10 000	250 000
Year class strengths	Lognormal	1.0	1.1	0.01	100
Trawl survey q	Lognormal	0.16	0.79	0.01	0.4
Selectivity (fishery)	Uniform	–	–	1	25–200*
Selectivity (survey, aI)	Normal-by-stdev	8	1	1	25
Selectivity (survey, aL , aR)	Normal-by-stdev	10	500	1	50–200*
M	Normal	0.19	0.2	0.1	0.35

* A range of maximum values was used for the upper bound

4.2.5 Model estimates

Estimates of biomass were produced for an agreed base case run (research survey abundance series, constant M) using the biological parameters and model input parameters described earlier. Sensitivity models were run to investigate the effects of estimating a constant M , including the CPUE series, and removing constraints on the survey selectivity ogive. Stock status from these three models was not markedly different to the base case. For all runs, MPD fits were obtained and qualitatively evaluated. Base case MCMC estimates of the median posterior and 95% percentile credible intervals are reported for virgin, current and projected biomass.

Estimated MCMC marginal posterior distributions from the base case model are shown for year class strengths (Figure 9) and biomass (Figure 10). The year class strength estimates suggested that the Chatham Rise stock was characterised by a group of relatively strong relative year class strengths in the late 1970s to early 1980s, and again in the early 1990s, followed by a period of relatively poor recruitment since then (except for 2002, 2010 and 2011). Consequently, biomass increased slightly during the late 1980s, then declined to about 2005. The growth of the strong 2002 year class resulted in an upturn in biomass from about 2006, followed by a further upturn from 2015 as the 2010 and 2011 year classes began to recruit. Current stock biomass was estimated at about 48% of B_0 (see Figure 10 and Table 14). Annual exploitation rates (catch over vulnerable biomass) were low (less than 0.1) up to 1993 and since 2006, but moderate (although probably less than 0.25) in the intervening period (Figure 11).

The resource survey and fishery selectivity ogives all had relatively wide bounds after age at peak selectivity. The survey ogive was essentially logistic (even though fitted as double normal) and had hake fully selected by the research gear from about age 9. Recall that age at full selectivity for the trawl survey was strongly influenced by tight priors. Fishing selectivities indicated that hake were fully selected in the western fisheries by about age 7 years, compared to age 11 in the eastern fishery; this is logical given that the eastern fishery concentrates more on the spawning (i.e., older) biomass.

Base case model projections assuming a future annual catch of 1800 t suggest that biomass will remain constant at about 48% of B_0 by 2021 (Table 15). There is little risk (i.e., < 1%) that the stock will fall below 20% B_0 in the next five years under this catch scenario. Note that 1800 t is higher than recent annual landings from the stock (they have averaged about 400 t in the last six years), but lower than what could be taken (if all the HAK 4 TACC plus some HAK 1 catch from the western Rise was taken). Future catches of 400 t per year will allow further stock rebuilding.

Table 14: Bayesian median and 95% credible intervals of B_0 , B_{2016} , and B_{2016} as a percentage of B_0 for the Chatham Rise model runs.

Model run	B_0	B_{2016}	$B_{2016} (\%B_0)$
Base case	30 080 (26 510–40 090)	14 540 (10 850–22 460)	48.2 (40.0–59.1)
Tight survey prior	32 620 (28 420–39 600)	16 000 (11 770–23 120)	49.4 (40.9–59.8)
Estimate M	32 500 (27 440–47 110)	19 020 (13 160–33 220)	58.0 (46.2–74.0)
CPUE	36 910 (30 760–64 230)	20 160 (14 910–40 510)	54.5 (46.8–64.7)

Table 15: Bayesian median and 95% credible intervals of projected B_{2021} , B_{2021} as a percentage of B_0 , and B_{2021}/B_{2016} (%) for the Chatham Rise model runs.

Model run	Future catch (t)	B_{2021}	$B_{2021} (\%B_0)$	$B_{2021}/B_{2016} (\%)$
Base	1 800	14 700 (8 850–25 600)	48.3 (32.3–69.6)	100 (75–132)
	400	19 170 (13 620–30 280)	63.7 (48.9–83.4)	132 (108–162)
Tight survey prior	1 800	16 560 (9 980–26 260)	50.3 (33.8–70.1)	101 (77–132)
	400	21 180 (14 810–31 800)	64.9 (49.2–84.1)	130 (107–160)
Estimate M	1 800	19 490 (11 570–35 640)	59.5 (39.9–87.0)	102 (78–133)
	400	23 770 (15 570–38 720)	72.5 (53.9–95.9)	124 (99–156)

	400	25 580 (17 920–49 950)	68.7 (54.7–89.3)	126 (104–156)

**Figure 9: Estimated posterior distributions of year class strengths for the Chatham Rise (HAK 4) base case. The dashed horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.****Figure 10: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for the Chatham Rise (HAK 4) base case model for absolute biomass and stock status (biomass as a percentage of B_0).**

Figure 11: Exploitation rates (catch over vulnerable biomass) for the Chatham Rise stock base case model.

4.2.6 Estimates of sustainable yields

CAY yield estimates were not reported because of the uncertainty of the estimates of absolute biomass.

4.3 HAK 7 (West coast, South Island)

A new assessment for HAK 7 was carried out in 2017 using fisheries data up to the end of the 2015–16 fishing year. The assessment used catch-at-age from the commercial fishery since 1989–90, a research survey series, a CPUE series from 2001 to 2015, and estimates of biological parameters. The selected CPUE series incorporated data collected by observers since the change in 2001 to a new regulatory and reporting regime (involving ACE), and so was considered less likely to be biased by variations in fishing behaviour and catch reporting behaviour.

The stock assessment for HAK 7 had been last updated using data up to the end of the 2010–11 fishing year (Horn 2011). The data inputs were commercial catch-at-age, the first two research survey biomass indices (in 2000 and 2012), and a CPUE series from 2001 to 2011.

4.3.1 Model structure

The model partitioned the WCSI stock population into unsexed age groups 1–30 with the last age group considered a plus group. The CPUE and survey biomass series were each included in separate models, and a constant M was used. The model was initialised assuming an equilibrium age structure at an unfished equilibrium biomass (B_0) in 1974, i.e., with constant recruitment set equal to the mean of the recruitments over the period 1973–2009. There were two double-normal selectivity-at-age ogives; commercial fishing selectivity, and survey selectivity (in the model incorporating the survey data). Selectivities were assumed constant across all years in the fishery and the surveys, and hence there was no allowance for possible annual changes in selectivity. A sensitivity to the survey data model investigated the effect of estimating a constant M ; the results were little different to those from the survey model and are not presented here.

Five-year biomass projections were made assuming future WCSI catches of 4 100 t annually (the mean annual catch from the last six years) and 7 700 t annually (the TACC). For each projection scenario, estimated future recruitment variability was sampled from actual estimates from 1973 to 2009 (a period including both high and low recruitment success), and from 2000 to 2009 (the last 10 estimates of year class strength comprising a period of relatively low recruitment success).

4.3.2 Fixed biological parameters and observations

Estimates and assumed values for biological parameters used in the assessments are given in Table 4. Variability in the Schnute age-length relationship was assumed to be lognormal with a constant CV of 0.1.

Commercial fishery catch-at-age observations were available for 1979 (fishing by RV *Wesermünde*) and 1989–90 to 2014–15 (observer data). Research survey biomass and proportions-at-age data (from the four surveys) were also fitted in the model. The catch history assumed in the model runs is shown in Table 3. Resource survey abundance indices are given in Table 16, and CPUE indices in Table 17.

Table 16: Research survey indices (and associated CVs) for the WCSI stock.

Year	Vessel	Biomass (t)	CV
2000	<i>Tangaroa</i>	803	0.13
2012	<i>Tangaroa</i>	583	0.12
2013	<i>Tangaroa</i>	331	0.17

2013–14	1.03	0.03
2014–15	1.15	0.03

4.3.3 Model estimation

Model parameters were derived using Bayesian estimation implemented using the general-purpose stock assessment program CASAL v2.30 (Bull et al 2012). For final model runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm.

The error distributions assumed were multinomial for the proportions-at-age and lognormal for all other data. Biomass indices had assumed CVs set equal to the sampling CV but with an additional process error of 0.2 applied. A process error CV of 0.30 for the CPUE series was estimated following Francis (2011). The multinomial observation error effective sample sizes for the at-age data were adjusted using the reweighting procedure of Francis (2011). Ageing error was assumed to occur for the observed proportions-at-age data, by assuming a discrete normally distributed error with a CV of 0.08.

Year class strengths were assumed known (and equal to one) for years before 1973 and after 2009, when inadequate or no catch-at-age data were available. Otherwise year class strengths were estimated under the assumption that the estimates from the model should average one.

MCMCs were estimated using 8×10^6 iterations, a burn-in length of 3×10^6 iterations, and with every 5000th sample kept from the final 5×10^6 iterations (i.e., a final sample of length 1000 was taken from the Bayesian posterior).

4.3.4 Prior distributions and penalty functions

The assumed prior distributions used in the assessment are given in Table 18. The priors for B_0 and year class strengths were intended to be relatively uninformed, and had wide bounds. Priors for all selectivity parameters were assumed to be uniform. The prior for the survey q was informative and was estimated using the Sub-Antarctic hake survey priors as a starting point (see Section 4.1.4) because the survey series in both areas used the same vessel and fishing gear. However, the WCSI survey area in the 200–800 m depth range in strata 0004 A–C and 0012 A–C comprised 12 928 km²; seabed area in that depth range in the entire HAK 7 biological stock area (excluding the Challenger Plateau) is estimated to be about 24 000 km². So because biomass from only 54% of the WCSI hake habitat was included in the indices, the Chatham Rise prior on μ was modified accordingly (i.e., $0.16 \times 0.54 = 0.09$), and the bounds were also reduced from [0.01, 0.40] to [0.01, 0.25]. Priors for all selectivity parameters were assumed to be uniform. The prior for M was assumed to be a normal distribution with a CV of 0.2 around a mean of 0.19.

A penalty function was used to constrain the model so that any combination of parameters that resulted in a stock size that was so low that the historical catch could not have been taken was strongly penalised.

Table 18: The assumed priors for key distributions (when estimated) for the WCSI stock assessment. The parameters are mean (in natural space) and CV for lognormal and normal priors.

Parameter description	Distribution	Parameters		Bounds	
B_0	Uniform-log	–	–	5 000	250 000
Year class strengths	Lognormal	1.0	1.1	0.01	100
Trawl survey q	Lognormal	0.09	0.79	0.01	0.25
CPUE q	Uniform-log	–	–	1e-8	1e-3
Selectivities	Uniform	–	–	0	20–200*
M	Normal	0.19	0.2	0.1	0.35

* A range of maximum values was used for the upper bound

4.3.5 Model estimates

Recent trends in the assessment relied on either CPUE data since 2001, or biomass data from four trawl surveys since 2000. The Working Group could not identify a base case model because the two relative abundance series exhibited conflicting trends in the most recent 5 years but were considered to be equally plausible. Consequently, estimates of biomass were produced for two models: the ‘survey’ model included all the research survey biomass estimates and catch-at-age data, but excluded the CPUE; the ‘CPUE’ model (included the CPUE series but excluded all the survey data). For all runs, MPD fits were obtained and qualitatively evaluated, and MCMC estimates of the median posterior and 95% percentile credible intervals were determined for current and virgin biomass, and projected states.

The estimated MCMC marginal posterior distributions from the two model runs are shown for year class strength (Figure 12) and biomass (Figure 13). WCSI year class strength estimates exhibit a relatively low level of between-year variation, although there was a period of generally less than average recruitment from 1993 to 2009 (although the CPUE model has recruitment around average levels from 2006 to 2009). In both models, estimated biomass declined throughout the late 1970s owing to relatively high catch levels, then increased through the mid-1980s concurrent with a marked decline in catch. Biomass then steadily declined from 1988 to around 2010 owing to higher levels of exploitation and the recruitment of year classes that were generally of below-average strength. The trends of the two models diverge from around 2010 when stock status in both was estimated to be about 25–30% of B_0 . The survey model indicates that biomass subsequently remained around this level owing to continued generally poor recruitment and relatively high exploitation rates (catch over vulnerable biomass) of 0.20–0.35 (Figure 14). Estimated current biomass from the Survey model was 26% B_0 (Figure 13, Table 19). The CPUE model has a steady stock recovery as a consequence of recruitment of several average year classes and relatively low exploitation rates (around 0.13). Estimated current biomass from the CPUE model was 50% B_0 (Figure 13, Table 19).

The median selectivity ogives for both the survey and the fishery were approximately logistic shaped, and their bounds were relatively wide. The ogives suggested that hake were fully selected by the fishery by about age 8, and slightly older in the survey.

In both models, the abundance series were reasonably well fitted. Likelihood profiling indicated that the fishery catch-at-age data dominated, but the CPUE data indicated a B_0 greater than 90 000 t, while the research survey data indicated a B_0 much lower than 90 000 t.

Table 19: Bayesian median (95% credible intervals) (MCMC) of B_0 , B_{2016} , and B_{2016} as a percentage of B_0 for the WCSI ‘survey’ and ‘CPUE’ models.

Model run	B_0		B_{2016}		B_{2016} (% B_0)	
Survey	79 190	(73 000–87 990)	20 490	(14 640–30 880)	25.7	(19.1–36.5)
CPUE	92 100	(81 410–131 360)	46 550	(29 190–87 710)	50.3	(34.6–73.6)

Figure 12: Estimated posterior distributions of year class strengths for the 'survey' and 'CPUE' models for the WCSI stock. The dashed horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

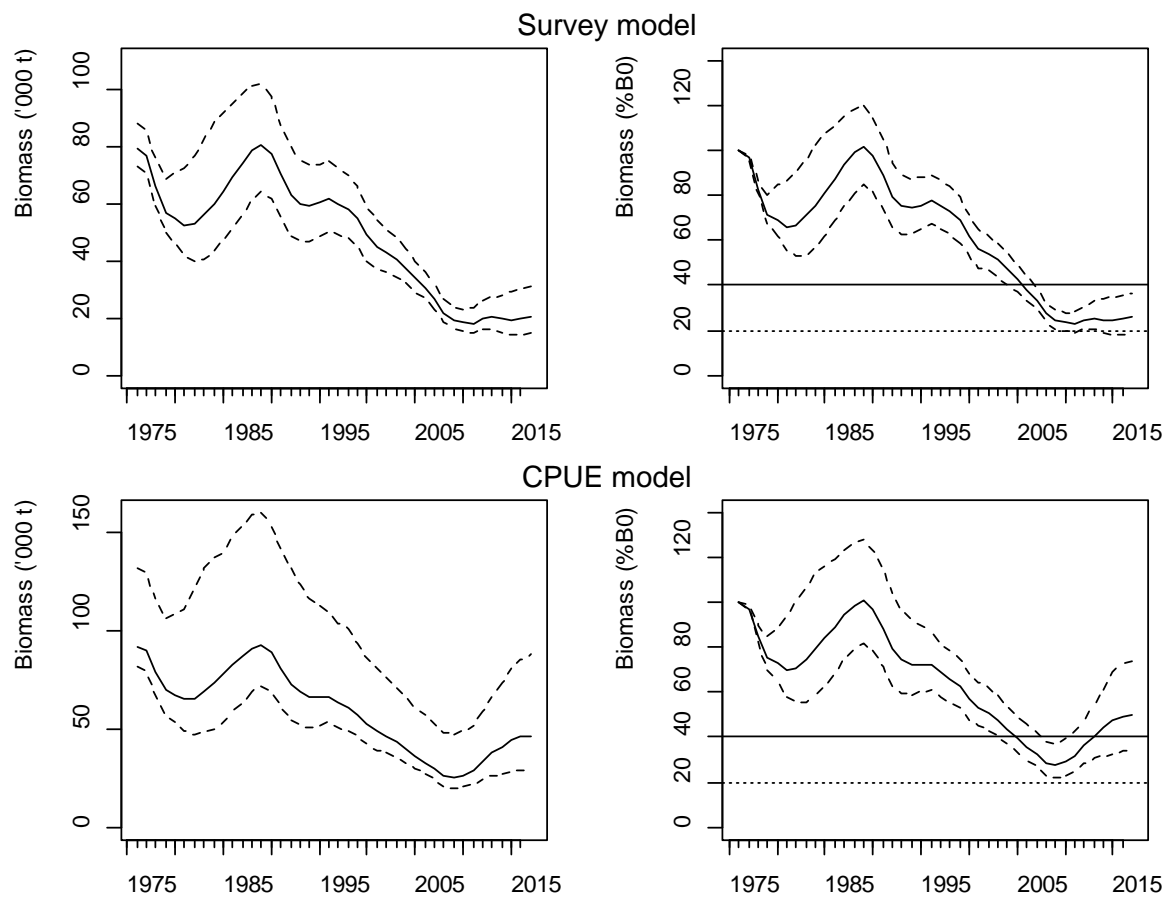

Figure 13: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for the WCSI stock 'survey' and 'CPUE' models for absolute biomass and biomass as a percentage of B_0 . The management target (40% B_0 , solid horizontal line) and soft limit (20% B_0 , dotted horizontal line) are shown on the right-hand panel.

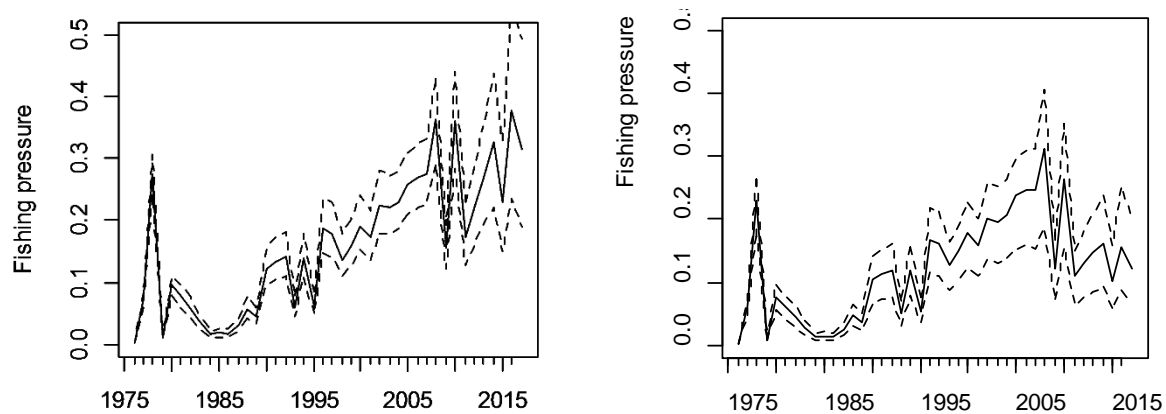

Figure 14: Exploitation rates for the WCSI stock ‘survey’ (left) and ‘CPUE’ models (right).

4.3.6 Yield estimates and projections

Projections assuming future catches similar to recent levels (i.e., 4100 t annually) will probably allow the stock to remain relatively constant or grow slightly in the next five years (dependent on future recruitment success), while catches at the level of the TACC (7700 t) will probably cause the stock to decline (Table 20). Under the survey model scenario, biomass in 2021 will probably be below the management target (40% B_0) and could be below the soft limit (20% B_0), while the CPUE model projects that biomass will be above the management target (40% B_0) in 2021 (Table 20).

Table 20: Bayesian median and 95% credible intervals of projected B_{2021} , B_{2021} as a percentage of B_0 , and B_{2021}/B_{2016} (%) for the ‘survey’ and ‘CPUE’ models, under two future annual catch scenarios and two future recruitment scenarios.

Future catch (t)	Future YC	B_{2016}		B_{2021}		$B_{2021} (\%B_0)$		$B_{2021}/B_{2016} (\%)$
Survey model								
4 100	2000–09	15 730	(8 640–28 270)	14 230	(5 900–30 150)	18.1	(7.4–36.2)	91 (55–133)

5. Status of the stocks

Stock Structure Assumptions

Hake are assessed as three independent biological stocks, based on the presence of three main spawning areas (eastern Chatham Rise, south of Stewart-Snares shelf, and WCSI), and some differences in biological parameters between these areas.

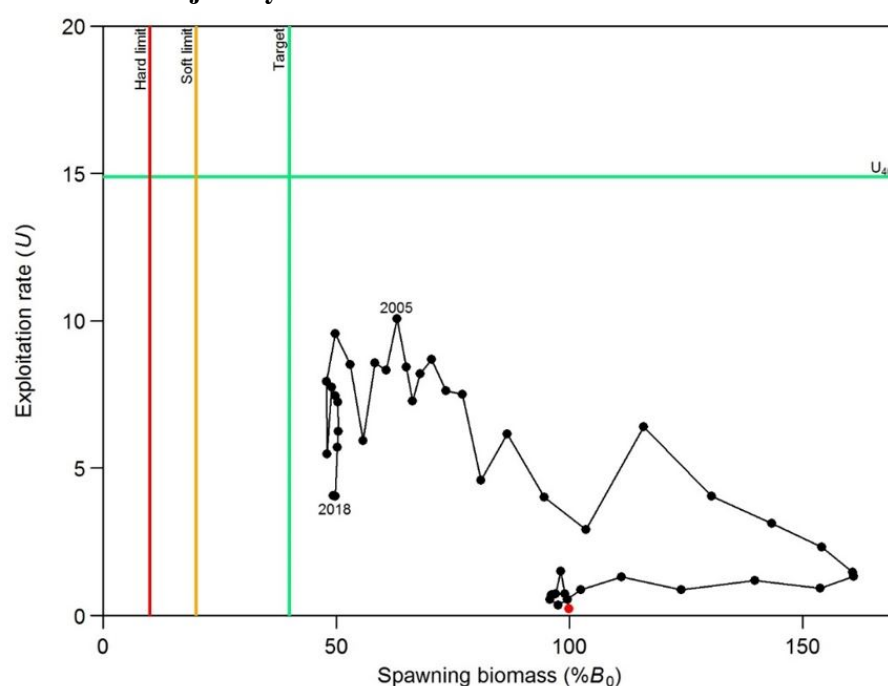

The HAK 1 Fishstock includes all of the Sub-Antarctic biological stock, part of the Chatham Rise biological stock, and all hake around the North Island (which are more likely part of either the WCSI or Chatham Rise stocks). The Sub-Antarctic stock is defined as all of Fishstock HAK 1 south of the Otago Peninsula; the Chatham Rise stock is all of HAK 4 plus that part of HAK 1 north of the Otago Peninsula; the WCSI stock is HAK 7.

HAKE (HAK)

- Sub-Antarctic Stock (HAK 1 South of Otago Peninsula)

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Base case
Reference Points	Management Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $U_{40\%}$
Status in relation to Target	B_{2018} was estimated at 49% B_0 ; Likely (> 60%) to be at or above the target
Status in relation to Limits	B_{2018} is Exceptionally Unlikely (< 1%) to be below both the Soft and Hard Limits
Status in relation to Overfishing	Overfishing is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory over time of exploitation rate (U) and spawning biomass ($\% B_0$), for the HAK 1 stock base model from the start of the assessment period in 1974 (represented by a red point), to 2018. The red vertical line at 10% B_0 represents the hard limit, the orange line at 20% B_0 is the soft limit, and green lines are the $\% B_0$ target (40% B_0) and the corresponding exploitation rate (U_{40}). Biomass and exploitation rate estimates are medians from MCMC results.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass is estimated to have been stable since 2010.
Recent Trend in Fishing Mortality or Proxy	Exploitation rate is estimated to have been low throughout the duration of the fishery.
Other Abundance Indices	A CPUE series showed a similar biomass trend to the research surveys.
Trends in Other Relevant Indicators or Variables	Recent year classes (since 2008) have been below average.

Projections and Prognosis (2019)

Stock Projections or Prognosis	The biomass of the Sub-Antarctic stock was expected to remain stable at recent average catch levels. At the TACC, the stock biomass is expected to decline.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)

Probability of Current Catch or TACC causing Overfishing to continue or to commence	Current catch: Extremely Unlikely (< 1%) TACC: Very Unlikely (< 10%)
---	---

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2018	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Research time series of abundance indices (trawl survey: summer, autumn) - Proportions-at-age data from the commercial fisheries and trawl surveys - Estimates of biological parameters 	1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	Commercial CPUE (used in sensitivity run only)	2 – Medium Quality: potentially biased owing to changes in fishing practice and catch reporting
Changes to Model Structure and Assumptions	This assessment now assumes constant M (rather than age-specific), and logistic selectivity for the fishery (rather than domed).	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - The summer trawl survey series has shown a decline over time, but individual survey estimates are variable and catchability clearly varies between surveys. The general lack of contrast in this series (the main relative abundance series) makes it difficult to accurately estimate past and current biomass. - The assumption of a single Sub-Antarctic stock (including the Puysegur Bank), independent of hake in all other areas, is the most parsimonious interpretation of available information. However, this assumption may not be correct. - Uncertainty about the size of recent year classes affects the reliability of stock projections. - There are patterns in the residuals in the commercial catch-at-age data fitted by the model. - Although the catch history used in the assessment has been corrected for some misreported catch (see Section 1.4), it is possible that additional misreporting exists. 	

Qualifying Comments
-

Fishery Interactions
Hake are often taken as a bycatch in hoki target fisheries. Some target fisheries for hake do exist, with the main bycatch species being hoki, ling, silver warehou and spiny dogfish. Hake are a key predator of hoki. Incidental interactions and associated mortality have been recorded for some protected species, including New Zealand fur seals and seabirds.

HAKE (HAK)

• Chatham Rise Stock (HAK 4 plus HAK 1 north of Otago Peninsula)

Stock Status	
Year of Most Recent Assessment	2017
Assessment Runs Presented	An agreed base case, fitted primarily to a research survey abundance series
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{40\%B_0}$
Status in relation to Target	B_{2016} was estimated to be about 48% B_0 ; Likely (> 60%) to be at or above target
Status in relation to Limits	B_{2016} is Exceptionally Unlikely (< 1%) to be below the Soft or Hard Limits
Status in relation to Overfishing	Overfishing is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the Chatham Rise hake stock from the start of the assessment period in 1975 to 2016 (the final assessment year). The management target (40% B_0 , solid horizontal line) and soft limit (20% B_0 , dotted horizontal line) are shown on the right-hand panel. Years on the x-axis indicate fishing year with “2005” representing the 2004–05 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Median estimates of biomass were below 40% B_0 from 2006 to 2014, but biomass has been slowly increasing since 2007.
Recent Trend in Fishing Intensity or Proxy	Fishing pressure is estimated to have been low since 2006 (relative to estimated pressure in most years from 1994 to 2005).
Other Abundance Indices	–
Trends in Other Relevant Indicators or Variables	Recruitment (1996–2013, but excluding 2002, 2010, and 2011) is estimated to be lower than the long-term average for this stock.

Projections and Prognosis	
Stock Projections or Prognosis	The biomass of the Chatham Rise stock is expected to increase over the next 5 years at catch levels equivalent to those from recent years (i.e., about 400 t annually), but is projected to remain constant if future catches are close to the high catch scenario (i.e. annual catch levels equivalent to the HAK 4 TACC of 1800 t).

Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Assuming future catches at the HAK 4 TACC: Soft Limit: Unlikely (< 20%) Hard Limit: Exceptionally unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Assuming future catches at the HAK 4 TACC: Unlikely (< 40%) Assuming future catches at the level of the current catch: Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2017	Next assessment: 2020?
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Research time series of abundance indices (trawl survey) - Proportions-at-age data from the commercial fisheries and trawl surveys - Estimates of biological parameters - New information since the 2013 assessment included two trawl surveys, and updated catch and catch-at-age data. 	1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	Commercial CPUE	2 – Medium or Mixed Quality: does track stock biomass well, and was used in a sensitivity model
Changes to Model Structure and Assumptions	- The model structure is unchanged from the previous assessment.	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Uncertainty about the size of recent year classes affects the reliability of stock projections. - Although the catch history used in the assessment has been corrected for some misreported catch (see Section 1.4), it is possible that additional misreporting exists. - It is assumed in the assessment models that natural mortality is constant over all ages. The use of dome-shaped fishery selectivity ogives will compensate for some variation in mortality rate with age. 	

Qualifying Comments
<p>The assumption of a single Chatham Rise stock independent of hake in all other areas is the most parsimonious interpretation of available information.</p> <p>The increase in relative abundance seen since 2006 is the result of good recruitment in 2002, 2010, and 2011.</p> <p>In October 2004, large catches were taken in the western deep fishery (i.e. near the Mernoo Bank). This has been repeated to a lesser extent in 2008 and 2010. There is no information indicating whether these aggregations fished on the western Chatham Rise were spawning; if they were then this might indicate that there is more than one stock on the Chatham Rise. However, the progressive increase in mean fish size from west to east is indicative of a single homogeneous stock on the Chatham Rise.</p>

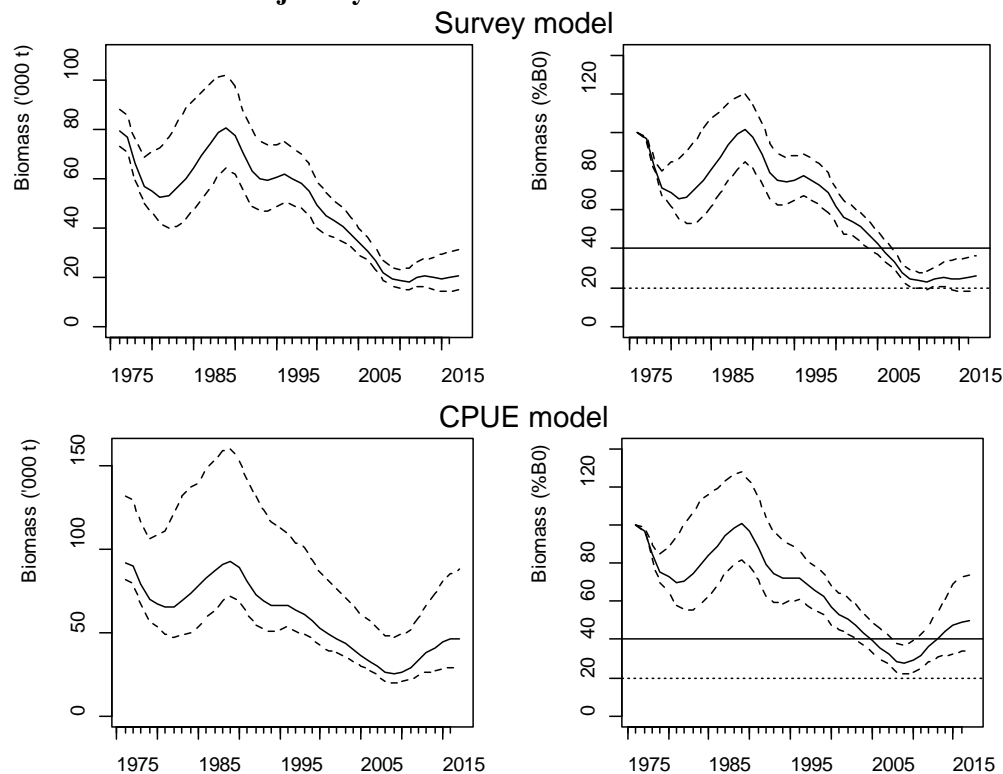

Fishery Interactions
Hake are often taken as a bycatch catch in hoki target fisheries. Some target fisheries for hake do exist, with the main bycatch species being hoki, ling, silver warehou and spiny dogfish. Hake are a

key predator of hoki. Incidental interactions and associated mortality have been recorded for some protected species, notably New Zealand fur seals and seabirds.

- West Coast South Island Stock (HAK 7)

Stock Status	
Year of Most Recent Assessment	2017
Assessment Runs Presented	Two alternative models, one fitting to the research trawl survey data, and the other to the CPUE series based on observer data
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{40\%B_0}$
Status in relation to Target	B_{2016} was estimated to be either 26% (survey model) or 50% (CPUE model) B_0 ; Either Very Unlikely (< 10%) to be at or above the target (survey model) or Very Likely (> 90%) to be at or above the target (CPUE model)
Status in relation to Limits	B_{2016} is About as Likely as Not (< 40–60%) to be below the Soft Limit and Very Unlikely (< 10%) to be below the hard Limit (survey model); and Very Unlikely (< 10%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit (CPUE model)
Status in relation to Overfishing	Overfishing in 2016 was Likely (> 60%) to be occurring (survey model) or Very Unlikely < 10%) to be occurring (CPUE model)

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the west coast South Island hake stock from the start of the assessment period in 1975 to 2016 (the final assessment year). Trajectories are presented for two alternative model runs. The management target (40% B_0 , solid horizontal line) and soft limit (20% B_0 , dotted horizontal line) are shown on the right-hand panels. Years on the x-axes indicate fishing year with “2005” representing the 2004–05 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	The CPUE mode shows an increasing trend since about 2010, and the survey model shows a flat trend from 2010.
Recent Trend in Fishing Intensity or Proxy	Fishing pressure is estimated to have been increasing in the survey model and flat in the CPUE model since 2010.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	Recent recruitment (2000–2009) is estimated to be lower than the long-term average for this stock. However, there is evidence in the survey and catch at age data that the 2014 year class may be stronger than the 2000–2009 average.

Projections and Prognosis	
Stock Projections or Prognosis	The biomass of the WCSI stock is expected to remain constant under recent recruitment and current catch, and to increase under average recruitment and recent catch for both the CPUE and the survey model. Under catches equal to the TACC, the biomass is expected to decline for both recruitment scenarios for both the CPUE and the survey models.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	For the survey model at current catches and average recruitment: Soft Limit: Unlikely (< 40%) Hard Limit: Very Unlikely (< 10%) For the CPUE model at current catches and average recruitment: Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	For the survey model at current catches and average recruitment: Soft Limit: Unlikely (< 40%) Hard Limit: Very Unlikely (< 10%) For the CPUE model at current catches and average recruitment: Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2017	Next assessment: 2020
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Trawl fishery CPUE since 2001 - Two comparable research trawl surveys (2000 and 2012, 2013, 2016) - Proportions-at-age data from the commercial fishery and two research surveys - Estimates of fixed biological parameters 	<ul style="list-style-type: none"> 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality

HAKE (HAK)

Data not used (rank)	- Trawl fishery CPUE prior to 2001	3 – Low Quality: may not track stock biomass
Changes to Model Structure and Assumptions	- The model structure is unchanged from the previous assessment, but the survey model included the additional survey biomass indices.	
Major sources of Uncertainty	<ul style="list-style-type: none">- The assumption of a single WCSI stock independent of hake in all other areas is the most parsimonious interpretation of available information.- Uncertainty about the size of recent year classes affects the reliability of stock projections.- Both biomass indices may not accurately reflect stock biomass- Although the catch history used in the assessment has been corrected for some misreported catch (see Section 1.4), it is possible that additional misreporting exists.- It is assumed in the assessment models that natural mortality is constant over all ages. The use of dome-shaped selectivity ogives will compensate for some variation in mortality rate with age.	
Qualifying Comments		
<p>The fishery-independent abundance series is sparse (i.e., four comparable trawl surveys), and these may not be an index of the total stock.</p> <p>CPUE from this stock has previously been considered too unreliable to be used as an abundance index, but a truncated series from 2001 has been used here under the assumption that any biases owing to changes in fishing or reporting behaviour are small.</p>		

Fishery Interactions
Hake are often taken as a bycatch catch in hoki target fisheries. Some target fisheries for hake do exist, with the main bycatch species being hoki, ling, silver warehou and spiny dogfish. Hake are a key predator of hoki. Incidental interactions and associated mortality have been recorded for some protected species, including New Zealand fur seals and seabirds.

Table 21: Summary of TACCs (t) and reported landings for the most recent fishing year.

Fishstock	QMA	2016–17 actual TACC	2016–17 reported landings
HAK 1	Auckland, Central Southeast, Southland, Sub-Antarctic (FMAs 1, 2, 3, 5, 6, 8, 9)	3 701	1 175

HOKI (HOK)*(Macruronus novaezelandiae)*

Hoki

**1. FISHERY SUMMARY****1.1 Commercial fisheries**

Historically, the main fishery for hoki operated from mid-July to late August on the west coast of the South Island (WCSI) where hoki aggregate to spawn. The spawning aggregations begin to concentrate in depths of 300–700 m around the Hokitika Canyon from late June, and further north off Westport later in the season. Fishing in these areas continues into September in some years. Starting in 1988, another major fishery developed in Cook Strait, where separate spawning aggregations of hoki occur. The spawning season in Cook Strait runs from late June to mid-September, peaking in July and August. Small catches of spawning hoki are taken from other spawning grounds off the east coast South Island (ECSI) and late in the season at Puysegur Bank.

Outside the spawning season, when hoki disperse to their feeding grounds, substantial fisheries have developed since the early 1990s on the Chatham Rise and in the Sub-Antarctic. These fisheries usually operate in depths of 300–800 m. The Chatham Rise fishery generally has similar catches over all months except in July–September, when catches are lower due to the fishery moving to the spawning grounds. In the Sub-Antarctic, catches have typically peaked in April–June. Out-of-season catches are also taken from Cook Strait and the east coast of the North Island, but these are small by comparison.

The hoki fishery was developed by Japanese and Soviet vessels in the early 1970s. Catches peaked at 100 000 t in 1977, but dropped to less than 20 000 t in 1978 when the EEZ was declared and quota limits were introduced (Table 1). From 1979 on, the hoki catch increased to about 50 000 t until an increase in the TACC from 1986 to 1990 saw the fishery expand to a maximum catch in 1987–88 of about 255 000 t (Table 2).

From 1986 to 1990, surimi vessels dominated the catches and took about 60% of the annual WCSI catch. However, after 1991, the surimi component of catches decreased and processing to head and gut, or to fillet product increased, as did “fresher” catch for shore processing. The hoki fishery now operates throughout the year, producing high quality fillet product from both spawning and non-

HOKI (HOK)

spawning fisheries. No surimi has been produced from hoki since 2002. Since 1998 twin-trawl rigs have operated in some hoki fisheries, and trawls made of spectra twine (a high strength twine with reduced diameter resulting in reduced drag and improved fuel efficiencies) were introduced to some vessels in 2007–08. Since 2012–13, precision seafood harvest (PSH) technology has been tested in the hoki fishery. This includes a prototype trawl system called a Modular Harvest System (MHS) that aims to target specific species and fish size, as well as enabling fish to be landed in much better condition than traditional trawls. The use of PSH in the hoki fishery is moving towards becoming “routine” although its use in high volume spawning aggregations is still problematic. To date, the proportion of catch taken by this gear method is still relatively small at 4019 t or 2.8% of the total catch in 2016–17.

Table 1: Reported trawl catches (t) from 1969 to 1987–88, 1969–83 by calendar year, 1983–84 to 1987–88 by fishing year (Oct–Sept). Source - FSU data.

* Catches for foreign licensed and New Zealand chartered vessels from 1978 to 1984 are based on estimated catches from vessel logbooks. Few data are available for the first 3 months of 1978 because these vessels did not begin completing these logbooks until 1 April 1978.

† Soviet hoki catches are taken from the estimated catch records and differ from official MAF statistics. Estimated catches are used because of the large amount of hoki converted to meal and not recorded as processed fish.

Table 2: Reported catch (t) from QMS, estimated catch (t) data, and TACC (t) for HOK 1 from 1986–87 to 2016–17. Reported catches are from the QMR and MHR systems. Estimated catches include TCEPR and CELR data (from 1989–90), LCER data (from 2003–04), NCELR data (from 2006–07), and TCER and LTCER data (from 2007–08). Catches are rounded to the nearest 500 t.

Year	Reported catch	Estimated catch	TACC
1986–1987	158 000	175 000	250 000
1987–1988	216 000	255 000	250 000

2015–2016	136 500	136 000	150 000
2016–2017	141 500	138 500	150 000

Note: Discrepancies between QMS data and actual catches from 1986 to 1990 arose from incorrect surimi conversion factors. The estimated catch in those years has been corrected from conversion factors measured each year by Scientific Observers on the WCSI fishery. Since 1990 the new conversion factor of 5.8 has been used, and the total catch reported to the QMS is considered to be more representative of the true level of catch.

Annual catches ranged between 175 000 and 215 000 t from 1988–89 to 1995–96, increasing to 246 000 t in 1996–97, and peaking at 269 000 t in 1997–98, when the TACC was over-caught by 19 000 t. Catches declined, tracking the TACC as it was reduced to address poor stock status, reaching a low of 89 000 t in 2008–09, then increasing again up to 161 500 t in 2014–15 following increases in the TACC as stock status improved (Table 2). The TACC was reduced to 150 000 t in 2015–16, and catches in the past two years have been below this (Table 2).

The pattern of fishing has changed markedly since 1988–89 when over 90% of the total catch was taken in the WCSI spawning fishery. This has been due to a combination of TAC changes and redistribution of fishing effort. The WCSI fishery accounted for about 47% of the total hoki catch in 2016–17, and has been the largest hoki fishery in New Zealand since 2011 (Table 3). Cook Strait catches peaked at 67 000 t in 1995–96, but have been relatively stable in the range from 15 000 to 20 000 t in the past 10 years. The Chatham Rise was the largest hoki fishery from 2006–07 to 2009–10, and contributed about 28% of the total catch in 2016–17. Catches from the Sub-Antarctic peaked at over 30 000 t from 1999–2000 to 2001–02, but have been variable since, ranging between 6 000 and 20 000 t over the past 15 years (Table 3).

Table 3: Estimated total catch (t) (scaled to reported QMR or MHR) of hoki by area 1988–89 to 2016–17 and based on data reported on TCEPR and CELR forms from 1988–89, but also including data reported on LCER (from 2003–04), NCELR (from 2006–07) and TCER and LTCER (both from 2007–08) forms. Catches from 1988–89 to 1997–98 are rounded to the nearest 500 t and catches from 1998–99 to 2016–17 are rounded to the nearest 100 t. Catches less than 100 t are shown by a dash.

HOKI (HOK)

From 1999–00 to 2001–02, there was a redistribution in catch from eastern stock areas (Chatham Rise, ECSI, ECNI, and Cook Strait) to western stock areas (WCSI, Puysegur, and Sub-Antarctic) (Table 4). This was initially due to industry initiatives to reduce the catch of small fish in the area of the Mernoo Bank, but from 1 October 2001 was part of an informal agreement with the Minister responsible for fisheries that 65% of the catch should be taken from the western fisheries to reduce pressure on the eastern stock. This agreement was removed following the 2003 hoki assessment in 2002–03, which indicated that the eastern hoki stock was less depleted than the western stock and effort was shifted back into eastern areas, particularly Cook Strait. From 2004–05 to 2006–07 there was an agreement with the Minister that only 40% of the catch should be taken from western fisheries and from 1 October 2007 the target catch from the western fishing grounds was further reduced to 25 000 t within the overall TACC of 90 000 t. This target was exceeded in both 2007–08 and 2008–09, with about 30 000 t taken from western areas (Table 3). In 2009–10, the target catch from the western fishing grounds was increased to 50 000 t within the overall TACC of 110 000 t, and catches were at about the industry-agreed catch split. Since then the target eastern catch has remained at 60 000 t, and the target western catch has further increased with changes in the overall TACC, up to a maximum of 100 000 t in 2014–15 (within the overall TACC 160 000 t). The western target catch in 2015–16 and 2016–17 was 90 000 t. The split between eastern and western catches has been within 2 000 t of the management targets since 2011–12, except in 2014–15 where the eastern catch was 4 600 t over the target, and in 2015–16 and 2016–17 where the western catches were lower than the target total by 13 400 t and 9 600 t respectively. Figure 1 shows the reported landings and TACC for HOK 1, and also the eastern and western catch components of this stock since 1988–89.

Table 4: Proportions of total catch for different fisheries.

Fishing Year	Spawning fisheries		Non-spawning fisheries	
	West	East	West	East

2016–2017	47%	15%	9%	29%

Total Allowable Commercial Catch (TACC) and area restrictions

In the 2016–17 fishing year, the TACC for HOK 1 was 150 000 t. This TACC applied to all areas of the EEZ (except the Kermadec FMA which had a TACC of 10 t). There was an agreement with the Minister responsible for fisheries that 90 000 t of the TACC should be taken from western stock areas and 60 000 t from the eastern stock areas. With the allowance for other mortality at 1 500 t and 20 t allowances for customary and recreational catch, the 2016–17 TAC was 151 540 t.

Vessels larger than 46 m in overall length may not fish inside the 12-mile Territorial Sea, and there are other various vessel size restrictions around some parts of the coast. On the WCSI, a 25-mile line closes much of the hoki spawning area in the Hokitika Canyon, and most of the area south to the Cook Canyon, to vessels larger than 46 m overall length. In Cook Strait, the whole spawning area is closed to vessels over 46 m overall length. In November 2007 the Government closed 17 Benthic Protection Areas (BPAs) to bottom trawling and dredging, representing about 30% of the EEZ and including depths that are outside the depth range of hoki.

The fishing industry introduced a Code of Practice (COP) for hoki target trawling in 2001 with the aim of protecting small fish (less than 60 cm). The main components of this COP were: 1) a restriction on fishing in waters shallower than 450 m; 2) a rule requiring vessels to 'move on' if there are more than 10% small hoki in the catch; and 3) seasonal and area closures in spawning fisheries. The COP was superseded by Operational Procedures for Hoki Fisheries, also introduced by the fishing industry from 1 October 2009. The Operational Procedures aim to manage and monitor fishing effort within four industry Hoki Management areas, where there are thought to be high abundances of juvenile hoki (Narrows Basin of Cook Strait, Canterbury Banks, Mernoo, and Puysegur). These areas are closed to trawlers over 28 m targeting hoki, with increased monitoring when targeting species other than hoki. There is also a general recommendation that vessels move from areas where catches of juvenile hoki (now defined as less than 55 cm total length) comprise more than 20% of the hoki catch by number.

2016–17 Hoki fishery

The overall catch of 141 567 t was almost 5 000 t higher than the catch in 2015–16, but about 8 500 t lower than the TACC (Table 3). Relative to 2015–16, catches in 2016–17 decreased in the main spawning areas and increased in non-spawning areas.

The WCSI catch decreased by 2 900 t to 66 000 t in 2016–17. Catches from inside the 25 n. mile line made up 25% of the total WCSI catch in 2016–17, an increase in proportion from 2015–16, but still lower than the peak of 41% of the catch taken inside-the-line in 2003–04. The WCSI fishing season is now longer – with fishing in May (although most pre-June catch is from inside the 25 n. mile line). Unstandardised catch rates on the WCSI in 2016–17 increased from 2015–16, with a median catch rate in all midwater tows targeting hoki of 5.5 t per hour. The WCSI catch in 2017 was dominated by fish from 55 to 110 cm from the 2007–14 year-classes (ages 3–10). There was a relatively high proportion of males from the 2014 year class (age 3), and 13% of hoki caught on the WCSI were less than 65 cm. From 1999–00 to 2003–04, the sex ratio of the WCSI catch was highly skewed, with many more females caught than males. In 2004–05 to 2010–11, as the catch of younger fish increased, the sex ratio reversed with more males than females caught. The sex ratio of the WCSI catch was about even in 2017, with 57% females. The mean length-at-age for hoki aged from 3–10 on the WCSI increased from the start of the fishery to the mid-2000s, but has since decreased.

The Chatham Rise fishery took 39 900 t in 2016–17, an increase of 3 200 t from 2015–16. Over 97% of the 2016–17 Chatham Rise catch was taken in bottom trawls, with the median unstandardised catch rate in bottom trawls targeting hoki of 1.4 t per hour. The length frequencies for both males and female hoki had modes at 40–50 cm from the 2015 year-class (age 1+), and at 50–65 cm from the 2014 year-class (ages 2+), with fewer larger, older fish. About 60% of the catch by number was less than 65 cm in 2016–17. Females comprised 56% of the catch.

The catch from Cook Strait of 16 100 t was down by about 2 300 t from that in 2015–16, and at a level similar to that in 2011–12. Peak catches were from mid-July to mid-September, with about 3 400 t caught outside the spawning season, and MHS trawls accounting for 2 900 t. Unstandardised catch rates in Cook Strait continued to be high - the median catch rate in midwater tows targeting hoki was 17.5 t per hour in 2016–17. Fish from a broad range of ages contributed to the fishery, with the main mode at ages 6–9 (2008 to 2011 year-classes) for females and ages 3–8 (2009 to 2014 year classes) for males. Only 12% of the catch was fish less than 65 cm. The sex ratio of the Cook Strait catch has fluctuated over time, with 49% males in the catch in 2016–17. As on the WCSI, the mean length at age in the Cook Strait fishery increased to the mid-2000s, but has subsequently declined.

The catch from the Sub-Antarctic of 13 200 t in 2016–17 was double that of the low catch in 2015–16. Most (86%) of the 2016–17 catch came from hoki target tows. Unstandardised catch rates in bottom trawls targeting hoki were 1.3 t per hour in 2016–17. Observer sampling in the Sub-Antarctic in 2016–

HOKI (HOK)

17 was not representative of the overall spatial and temporal distribution of the catch: deeper tows were under-sampled; and there was little coverage in Statistical Area 603. The observed catch included hoki of 35–45 cm from the 2015 year-class (age 1+), fish from 50–65 cm from the 2014 year class (age 2+), and fish from 65–90 cm primarily from ages 3–10. About 44% of the observed Sub-Antarctic catch was fish less than 65 cm, and about 60% of the catch were females.

Catches from Puysegur, ECNI and ECSI in 2016–17 were similar to those in 2015–16 at 1200 t, 800 t, and 4 400 t respectively.

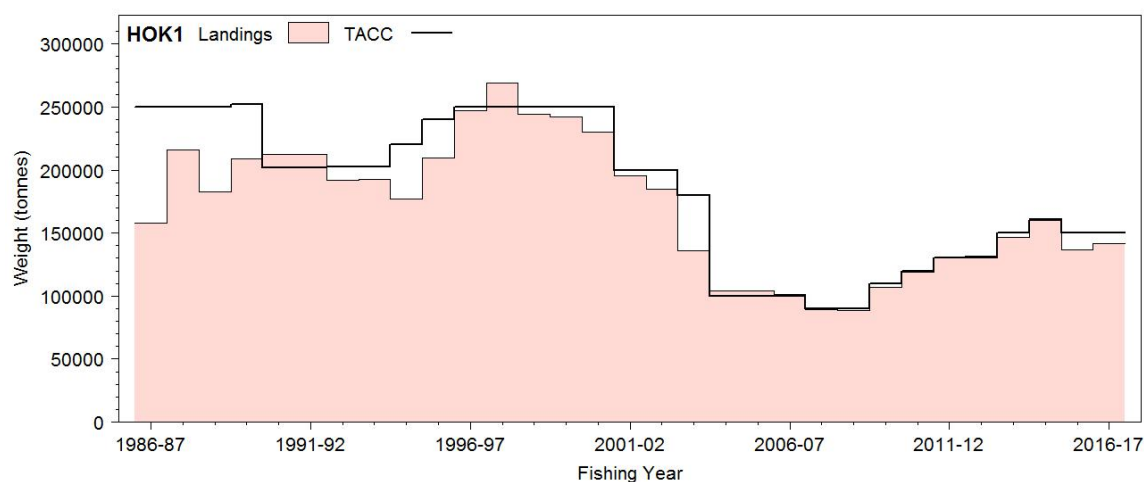

Figure 1a: Reported commercial landings and TACCs for HOK 1 since 1986–87. Note that this graph does not show data prior to entry into the QMS.

Figure 1b: The eastern and western components of the total HOK 1 landings since 1988–89. Note that these figures do not show data prior to entry into the QMS.

1.2 Recreational fisheries

Recreational fishing for hoki is negligible.

1.3 Customary non-commercial fisheries

The level of this fishery is believed to be negligible.

1.4 Illegal catch

No information is available about illegal catch.

1.5 Other sources of fishing mortality

There are a number of potential sources of additional fishing mortality in the hoki fishery:

In the years just prior to the introduction of the EEZ, when large catches were first reported, and following the increases of the TACC in the mid-1980s, it is likely that high catch rates on the west coast, South Island spawning fishery resulted in burst bags, loss of catch and some mortality. Although burst bags were recorded by some scientific observers, the extent of fish loss has not been estimated, however, the occurrence was at a sufficient level to result in the introduction of a code of practice to minimise losses in this way. Based on observer records from the period 2000–01 to 2006–07, Ballara et al (2010) noted that fish lost from the net during landing accounted for only a small fraction (0–14.5%) of the total fish discards each year in the hoki, hake and ling fishery.

- The use of escape panels or windows part way along the net that was developed to avoid burst bags may also in itself result in some mortality of fish that pass through the window. The extent of these occurrences and the historical and current use of such panels/windows have not been quantified.
- The development of the fishery on younger hoki (2 years and over) on the Chatham Rise from the mid-1990s and the prevalence of small hoki in catches on the WCSI in recent years may have resulted in some discarding of small fish.
- Overseas studies indicate that large proportions of small fish can escape through trawl meshes during commercial fishing and that the mortality of escapees can be high, particularly among species with deciduous scales (scales that shed easily) such as hoki. Selectivity experiments in the 1970s indicated that the 50% selection length for hoki for a 100 mm mesh codend is about 57–65 cm total length (Fisher 1978, as reported by Massey & Hore 1987). Research using a twin-rig trawler in June 2007 estimated that the 50% selection length was somewhat lower at 41.5 cm with a selection range (length range between 25% and 75% retention) of 14.3 cm (Haist et al 2007). Applying the estimated retention curve to scaled length frequency data for the Chatham Rise fishery suggested that annually between 47 t (in 1997–98) and 4287 t (in 1995–96) of hoki may have escaped commercial fishing gear. More recent research comparing the selectivity of 100 mm and MHS codends in June 2017 suggested similar mean 50% selection lengths of about 48–49 cm for both gears, but with the MHS gear having a narrower selection range (11.7 cm compared to 14.8 cm for 100 mm codend) (O’Driscoll & Millar 2017). Net damaged adult hoki have been recorded in the WCSI fishery in some years indicating that there may be some survival of escapees. The extent of damage and resulting mortality of fish passing through the net is unknown.

These sources of additional fishing mortality are not incorporated in the current stock assessment.

2. BIOLOGY

Hoki are widely distributed throughout New Zealand waters from 34° S to 54° S, from depths of 10 m to over 900 m, with greatest abundance between 200 and 600 m. Large adult hoki are generally found deeper than 400 m, while juveniles are more abundant in shallower water. In the January 2003 Chatham Rise trawl survey, exploratory tows with mid-water gear over a hill complex east of the survey area found low density concentrations of hoki in mid-water at 650 m over depths of 900 m or greater (Livingston et al 2004). The proportion of larger hoki outside the survey grounds is unknown. Commercial data also indicate that larger hoki have been targeted over other hill complexes outside the survey areas of both the Chatham Rise and Sub-Antarctic (Dunn & Livingston 2004), and have also been caught as a bycatch by tuna fishers over very deep water (Bull & Livingston 2000).

The two main spawning grounds on the WCSI and in Cook Strait are considered to comprise fish from separate stocks, based on the geographical separation of these spawning grounds and a number of other factors (see Section 3 “Stocks and areas” below).

Hoki migrate to spawning grounds in Cook Strait, WCSI, Puysegur, and ECSI areas in the winter months. Throughout the rest of the year the adults are dispersed around the edge of the Stewart and Snares shelf, over large areas of the Sub-Antarctic and Chatham Rise, and to a lesser extent around the North Island. Juvenile fish (2–4 yrs) are found on the Chatham Rise throughout the year.

HOKI (HOK)

Hoki spawn from late June to mid-September, releasing multiple batches of eggs. They have moderately high fecundity with a female of 90 cm TL spawning over 1 million eggs in a season (Schofield & Livingston 1998). Not all hoki within the adult size range spawn in a given year. Winter surveys of both the Chatham Rise and Sub-Antarctic have found significant numbers of large hoki with no gonad development, at times when spawning is occurring in other areas. Histological studies of female hoki from the Sub-Antarctic in May 1992 and 1993 estimated that 67% of hoki aged 7 years and older on the Sub-Antarctic would spawn in winter 1992, and 82% in winter 1993 (Livingston et al 1997). A similar study repeated in April 1998 found that a much lower proportion (40%) of fish aged 7 and older was developing to spawn (Livingston & Bull 2000). Reanalysis of the 1998 data has shown that there is a correlation between stratum and oocyte development (Francis 2009). A new method, developed to estimate proportion spawning from summer samples of post-spawner hoki in the Sub-Antarctic, indicated that approximately 85% of the hoki aged 4 years and older from 2003–2004 had spawned (Grimes & O'Driscoll 2006, Parker et al 2009).

The main spawning grounds are centred on the Hokitika Canyon off the WCSI and in Cook Strait Canyon. The planktonic eggs and larvae move inshore by advection or upwelling (Murdoch 1990; Murdoch 1992) and are widely dispersed north and south with the result that 0+ and 1-year-old fish can be found in most coastal areas of the South Island and parts of the North Island. The major nursery ground for juvenile hoki aged 2–4 years is along the Chatham Rise, in depths of 200 to 600 m. The older fish disperse to deeper water and are widely distributed in both the Sub-Antarctic and Chatham Rise. Analyses of trawl survey (1991–02) and commercial data suggests that a significant proportion of hoki move from the Chatham Rise to the Sub-Antarctic as they approach maturity, with most movement between ages 3 and 7 years (Bull & Livingston 2000, Livingston et al 2002). Based on a comparison of RV *Tangaroa* trawl survey data, on a proportional basis (assuming equal catchability between areas), 80% or more of hoki aged 1–2 years occur on the Chatham Rise. Between ages 3 and 7, this drops to 60–80%. By age 8, 35% or fewer fish are found on the Chatham Rise compared with 65% or more in the Sub-Antarctic. A study of the observed sex ratios of hoki in the two spawning and two non-spawning fisheries found that in all areas, the proportion of male hoki declines with age (Livingston et al 2000). There is little information at present to determine the season of movement, the exact route followed, or the length of time required, for fish to move from the Chatham Rise to the Sub-Antarctic. Bycatch of hoki from tuna vessels following tuna migrations from the Sub-Antarctic showed a northward shift in the incidence of hoki towards the WCSI in May-June (Bull & Livingston 2000). The capture of net-damaged fish on Pukaki Rise following the WCSI spawning season where there had been intense fishing effort in 1989 also provides circumstantial evidence that hoki migrate from the WCSI back to the Sub-Antarctic post-spawning (Jones 1993).

Growth is fairly rapid with juveniles reaching about 27–35 cm TL at the end of the first year. There is evidence for changing growth rates over time. In the past, hoki reached about 45, 55 and 60–65 cm TL at ages 2, 3, and 4 respectively, but in the mid-2000s length modes were centred at 50, 60, and 70 cm TL for ages 2, 3, and 4. Recently growth has slowed, and is intermediate between these two levels. Although smaller spawning fish are taken on the spawning grounds, males appear to mature mainly from 60–65 cm TL at 3–5 years, while females mature at 65–70 cm TL. From the age of maturity the growth of males and females differs. Males grow up to about 115 cm TL, while females grow to a maximum of 130 cm TL and up to 7 kg weight. Horn & Sullivan (1996) estimated growth parameters for the two stocks separately (Table 5). Fish from the eastern stock sampled in Cook Strait are smaller on average at all ages than fish from the WCSI. Maximum age is from 20–25 years, and the instantaneous rate of natural mortality in adults is about 0.25 to 0.30 per year.

There is evidence that ageing error causes problems in the estimation of year class strength. For example, the 1989 year class appeared as an important component in the catch at age data at older ages, yet this year class is believed to have been extremely weak in comparison to the preceding 1988 and 1987 year classes. An improved ageing protocol was developed to increase the consistency of hoki age estimation and this has been applied to the survey data from 2000 onwards and to catch samples from 2001 (Francis 2001). Data from earlier samples, however, are still based on the original methodology and otolith readings.

Estimates of biological parameters relevant to stock assessment are shown in Table 5 (but note that natural mortality was estimated in the model in the assessment).

Table 5: Estimates of fixed biological parameters.

Fishstock				Estimate	Source

3. STOCKS AND AREAS

Morphometric and ageing studies have found consistent differences between adult hoki taken from the two main dispersed areas (Chatham Rise and Sub-Antarctic), and from the two main spawning grounds in Cook Strait and WCSI (Livingston et al 1992, Livingston & Schofield 1996b, Horn & Sullivan 1996). These differences clearly demonstrate that there are two sub-populations of hoki. Whether or not they reflect genetic differences between the two sub-populations, or they are just the result of environmental differences between the Chatham Rise and Sub-Antarctic, is not known. No genetic differences have been detected with selectively neutral markers (Smith et al 1981, 1996) but a low exchange rate between stocks could reduce genetic differentiation.

Two pilot studies appeared to provide support for the hypothesis of spawning stock fidelity for the Cook Strait and WCSI spawning areas. Smith et al (2001) found significant differences in gill raker counts, and Hicks & Gilbert (2002) found significant differences in measurements of otolith rings, between samples of 3 year-old hoki from the 1997 year-class caught on the WCSI and in Cook Strait. However, when additional year-classes were sampled, differences were not always detected (Hicks et al 2003). It appears that there are differences in the mean number of gill rakers and otolith measurements between stocks, but, due to high variation, large sample sizes would be needed to detect these (Hicks et al 2003). Francis et al (2011) carried out a pilot study to determine whether analyses of stable isotopes and trace elements in otoliths could be useful in testing stock structure hypotheses and the question of natal fidelity. However, none of the six trace elements or two stable isotopes considered unambiguously differentiated the two stocks.

The DWWG has assessed the two spawning groups as separate stock units. The west coast of the North and South Islands and the area south of New Zealand including Puysegur, Snares and the Sub-Antarctic has been taken as one stock unit (the "western stock"). The area of the ECSI, Mernoo Bank, Chatham Rise, Cook Strait and the ECNI up to North Cape has been taken as the other stock unit (the "eastern stock").

4. CLIMATE AND RECRUITMENT

Annual variations in hoki recruitment have considerable impact on this fishery and a better understanding of the influence of climate on recruitment patterns would be very useful for the future projection of stock size. However, any link between climate, oceanographic conditions and recruitment is still unknown. Analyses by Francis et al (2006) do not support the conclusions of Bull & Livingston (2001) that model estimates of recruitment to the western stock are strongly correlated with the southern oscillation index (SOI). Francis et al (2006) noted that there is a correlation of -0.70 between the autumn SOI and annual estimates of recruitment (1+ and 2+ fish) from the Chatham Rise trawl survey but found this hard to interpret because the survey is an index of the combined recruitment to both the eastern and western stocks. A more recent analysis supports some climate effect on hoki recruitment but remains equivocal about its strength or form (Dunn et al 2009b). Bradford-Grieve & Livingston (2011) collated and reviewed information on the ocean environment on the WCSI in relation to hoki and other spawning fisheries. Hypotheses about which variables drive hoki recruitment

were presented, but the authors noted that understanding of the underlying mechanisms and causal links between the WCSI marine environment and hoki year class survival remain elusive.

A baseline report summarising trends in climatic and oceanographic conditions in New Zealand that are of potential relevance for fisheries and marine ecosystem resource management in the New Zealand region has been completed (Hurst et al 2012). There is also a chapter on oceanic trends in the Aquatic Environment & Biodiversity Annual Review 2017 (MPI 2017). The effects of marine heatwaves on fisheries, such as that experienced in New Zealand summer 2017-18, have yet to be reported.

5. ENVIRONMENTAL AND ECOSYSTEM CONSIDERATIONS

This section was last fully reviewed by the Aquatic Environment Working Group for the May 2012 Fishery Assessment Plenary. However, the tables have been updated with more recent data, where available, and minor corrections made for the 2018 report. This summary is from the perspective of the hoki fishery; a more comprehensive review from an issue-by-issue perspective is available in the 2017 Aquatic Environment & Biodiversity Annual Review (MPI 2017: <https://www.mpi.govt.nz/dmsdocument/27471-aquatic-environment-and-biodiversity-annual-review-aebar-2017-a-summary-of-environmental-interactions-between-the-seafood-sector-and-the-aquatic-environment>).

5.1 Role in the ecosystem

Hoki is the species with the highest biomass in the bottom fish community of the upper slope (200–800 m), particularly around the South Island (Francis et al 2002), and is considered to be a key biological component of the upper slope ecosystem. Understanding the predator-prey relationships between hoki and other species in the slope community is important, particularly since substantial changes in the biomass of hoki have taken place since the fishery began. Other metrics including ecosystem indicators can also provide insight into fishery interactions with target and non-target fish populations. For example, changes in growth rate can be indicative of density-dependent compensatory mechanisms in response to changes in population density.

5.1.1 Trophic interactions

On the Chatham Rise, hoki is a benthopelagic and mesopelagic forager, preying primarily on lantern fishes and other mid-water fishes and natant decapods with little seasonal variation (Clark 1985a, b, Dunn et al 2009a, Connell et al 2010, Stevens et al 2011). Hoki show ontogenetic shifts in their feeding preferences, and larger hoki (over 80 cm) consume proportionately more fish and squid than do smaller hoki (Dunn et al 2009a, Connell et al 2010). The diet of hoki overlaps with those of alfonsoino, arrow squid, hake, javelinfish, Ray's bream, and shovelnose dogfish (Dunn et al 2009a). Hoki are prey to several piscivores, particularly hake but also stargazers, smooth skates, several deep water shark species, and ling; (Dunn et al 2009a). The proportion of hoki in the diet of hake averages 38% by weight, and has declined since 1992 (Dunn & Horn 2010), possibly because of a decline in the relative abundance of hoki on the Chatham Rise between 1991 and 2007. There is little information about the size of hoki eaten by predators (i.e. specifically whether the hoki are large enough to have recruited to the fishery or not), but this could be an important factor in understanding the interaction with the fishery and the potential for competition.

5.1.2 Ecosystem Indicators

Tuck et al (2009) used data from the Sub-Antarctic and Chatham Rise trawl survey series to derive fish-based ecosystem indicators using diversity, fish size, and trophic level. Species-based indicators appeared the most useful in identifying changes correlated with fishing intensity; Pielou's evenness appears the most consistent but the Shannon-Wiener index, species richness, and Hill's N1 and N2 also showed some promise (Tuck et al 2009). Trends in diversity in relation to fishing are not necessarily downward, and depend on the nature of the community. Size-based indicators did not appear as useful for New Zealand trawl survey series as they have been overseas, and this may be related to the requirement to consider only measured species. In New Zealand, routine measurement of all fish species in trawl surveys was implemented in 2008 and this may increase the utility of size-based indicators in the future.

Between 1992 and 1999 the growth rates of all year classes of hoki increased by 10% in all four fishery areas but it is unclear whether this was a result of reduced competition for food within and among cohorts or some other factor (Bull & Livingston 2000). The abundance of mesopelagic fish, a major prey item for hoki, has the potential to be an indicator of food availability. Recent research using acoustic backscatter data collected during trawl surveys has shown no clear temporal trend in mesopelagic fish biomass on the Chatham Rise between 2001 and 2009, but a decline for the Sub-Antarctic area from 2001 to 2007, followed by an increase in 2008 and 2009. The abundance of mesopelagic fish is consistently much higher on the Chatham Rise than in the Sub-Antarctic, with highest densities observed on the western Chatham Rise and lowest densities on the eastern Campbell Plateau (O'Driscoll et al 2011a). Spatial patterns in mesopelagic fish abundance closely matched the distribution of hoki. O'Driscoll et al (2011a) hypothesise that prey availability influences hoki distribution, but that hoki abundance is being driven by other factors such as recruitment variability and fishing. There was no evidence for a link between hoki condition and mesopelagic prey abundance and there were no obvious correlations between mesopelagic fish abundance and environmental indices.

5.2 Bycatch (fish and invertebrates)

The main commercial bycatch species in hoki target fisheries off the west coast South Island, Chatham Rise and Sub-Antarctic are hake, ling, silver warehou, jack mackerel and spiny dogfish. In Cook Strait, the main commercial bycatch species are ling and spiny dogfish. From 1990–91 to 2012–13, hoki, hake, and ling accounted for 91% of the total observed catch from trawls targeting these species. These three species made up 90%, 1%, and 2%, respectively, of the catch in target hoki trawls between 2008–09 and 2012–13 (Table 6). The hoki-hake-ling fishery is complex, and changes in fishing practice are likely to have contributed to variability between years (Ballara & O'Driscoll, 2015b).

Table 6: Raw catch weight and percentage by weight of species taken in hoki trawls with an observed catch of > 20 t by fishing year. Data from the Central Observer Database.

Species	2010–11		2011–12		2012–13		2013–14		2014–15	
	Catch (t)	%	Catch (t)	%	Catch (t)	%	Catch (t)	%	Catch (t)	%

Others	305	1.3	510	1.4	1 334	2.1	1499	2.6	1149	2.3

5.3 Incidental capture of Protected Species (seabirds, mammals, and protected fish)

For protected species, capture estimates presented here include all animals recovered to the deck (alive, injured or dead) of fishing vessels but do not include any cryptic mortality (e.g., seabirds struck by a warp but not brought on board the vessel, Middleton & Abraham 2007).

HOKI (HOK)

New Zealand fur seal interactions

The New Zealand fur seal was classified in 2008 as “Least Concern” by the International Union for Conservation of Nature (IUCN) and in 2010 as “Not Threatened” under the New Zealand Threat Classification System (Baker et al 2016).

Vessels targeting hoki incidentally catch fur seals (Baird 2005b, Smith & Baird 2009, Thompson & Abraham 2010a, Baird 2011, Abraham et al 2016). The lowest capture rates have occurred in the most recent years (Table 7). Observed captures have occurred mostly off the west coast South Island and in the Cook Strait. Estimated captures of New Zealand fur seals in the hoki fishery have accounted for 44% of all fur seals estimated to have been caught by trawling in the EEZ between 2002–03 and 2016–17 for those fisheries modelled. However, this model may be over-estimating the upper bound of the confidence interval of estimated captures, perhaps reflecting inappropriate partitioning of the estimate between strata with contrasting capture rates (a problem that is known to have affected similar fur seal capture models e.g. in SBW fisheries). Consequently, annual capture estimates in Table 7 should be interpreted with caution until the structure of this model is evaluated in greater detail.

Table 7: Number of tows by fishing year and observed and model-estimated total New Zealand fur seal captures in hoki trawl fisheries, 1998–99 to 2015–16. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows, % inc, percentage of total effort included in the statistical model. * Estimates 1998–99 to 2001–02 from Smith & Baird (2009) who estimated captures by area and confidence intervals have not been estimated at this level of aggregation. Other estimates are based on methods described in Abraham et al (2016) and available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 20170001.

New Zealand sea lion interactions

The New Zealand (or Hooker’s) sea lion was classified in 2008 as “Vulnerable” by IUCN and in 2016 as “Nationally Critical” under the New Zealand Threat Classification System (Baker et al 2016). Pup production at the main rookeries has shown a steady decline since the late 1990s.

New Zealand sea lions are captured only rarely by vessels trawling for hoki, the highest recorded rate in the last 15 years being 0.05 sea lions per 100 tows and with a total of only five animals observed captured since 1998–99 (Table 8, MPI 2013). All observed captures have been close to the Auckland Islands or nearby.

Table 8: Number of tows by fishing year and observed New Zealand sea lion captures in hoki trawl fisheries, 2002–03 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows. Estimates are based on methods described in Abraham et al (2016) and available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 2017v1.

Seabird interactions

Vessels targeting hoki incidentally catch seabirds, with information on observed captures summarised for 1998–99 to 2002–03 by Baird (2005a), for 2003–04 to 2005–06 by Baird & Smith (2007, 2008), for 1989–90 to 2008–09 by Abraham & Thompson (2011) and for Abraham et al 2016.

A consistent modelling framework was developed to estimate the captures for ten species (and species groups), using hierarchical mixed-effects generalised linear model (GLM), fitted using Bayesian methods (Abraham et al 2016, Abraham & Richard 2017, 2018). In the 2015–16 fishing year there were 48 observed captures of seabirds in hoki trawl fisheries. In the same year it was estimated by a statistical model that there were a total of 238 (95% c.i. 184–311) captures in hoki trawl fisheries. In the 2016–17 fishing year, 59 seabird captures were observed in hoki trawl fisheries; the estimate of total captures is not yet available (Table 9). Annual observed seabird capture rates have ranged between 1.3 and 4 per 100 tows in the hoki fishery over the time period 2002–03 and 2016–17, with little apparent trend. These estimates include all seabird species and all methods of capture and should be interpreted with caution. The average capture rate in hoki trawl fisheries for the period from 2002–03 to 2015–16 is about 2.32 birds per 100 tows, a low rate relative to other New Zealand trawl fisheries; e.g. for scampi (4.43 birds per 100 tows) and squid (13.79 birds per 100 tows) over the same years.

Table 9: Number of tows by fishing year and observed and model-estimated total seabird captures in hoki trawl fisheries, 1998–99 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows, % inc, percentage of total effort included in the statistical model. Estimates are based on methods described in Abraham et al (2016) and Abraham & Richard (2017, 2018) and available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 2017v01.

HOKI (HOK)

Observed seabird captures since 2002–03 have been dominated by six species: Salvin’s, southern Buller’s, and New Zealand white-capped albatrosses make up 45%, 27%, and 22% of the albatrosses captured, respectively; and sooty shearwaters, white-chinned petrels, and cape petrels make up 58%, 23%, and 6% of other birds, respectively (Table 10). The highest proportions of captures have been observed off the east coast of the South Island (50%), on the Stewart-Snares shelf (20%), on the Chatham Rise (11%), and off the west coast of the South Island (9%). These numbers should be regarded as only a general guide on the distribution of captures because observer coverage is not uniform across areas and may not be representative.

The hoki target fishery contributes to the total risk posed by New Zealand commercial fishing to seabirds (see Table 10). The two species to which the fishery poses the most risk are Southern Buller’s albatross and Salvin’s albatross, with this target fishery poses 0.14 and 0.12 of PST (Table 11). Southern Buller’s albatross and Salvin’s albatross were both assessed at high risk (Richard et al 2017).

Mitigation methods such as streamer (tori) lines, Brady bird bafflers, warp deflectors, and offal management are used in the hoki trawl fishery. Warp mitigation was voluntarily introduced from about 2004 and made mandatory in April 2006 (Department of Internal Affairs, 2006). The 2006 notice mandated that all trawlers over 28 m in length use a seabird scaring device while trawling (being “paired streamer lines”, “bird baffler” or “warp deflector” as defined in the notice).

The three year average warp capture rate of Salvin’s and white-capped albatross before warp mitigation was made mandatory at the start of the 2005–06 fishing year was 0.38 per 100 tows in hoki target trawls, the three year average was lowest for the period 2005–06 to 2007–08. Since then the three year warp capture rate has increased to 0.27 per 100 tows for 2011–12 to 2013–14, and was 0.21 for 2013–14 to 2015–16. For these same species the three year average capture rates from nets has increased steadily over this time period (Figure 2).

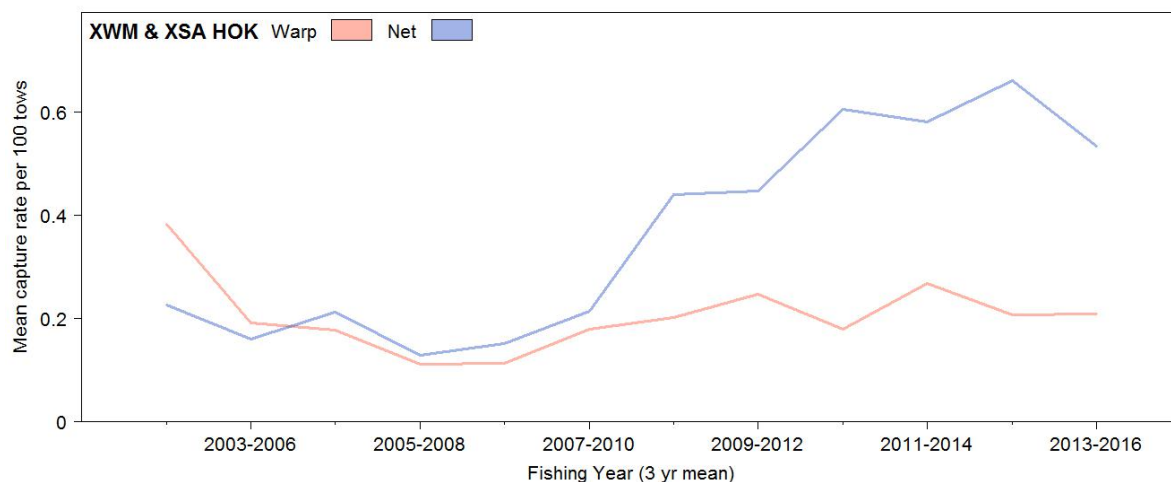

Figure 2: Three year rolling average of capture rates of white-capped albatross in squid trawl fisheries for warp and net captures.

Table 10: Number of observed seabird captures in hoki trawl fisheries, 2002–03 to 2016–17, by species and area. The risk category is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the Population Sustainability Threshold, PST (from Richard et al 2017, where full details of the risk assessment approach can be found). It is not an estimate of the risk posed by trawl fishing for hoki alone.

	Risk category	East Coast South Island	West Coast South Island	Stewart Snares Shelf	Chatham Rise	Cook Strait	Fiordland	Subantarctic	Auckland Islands	Bay of Plenty	Total

Basking shark interactions

The basking shark was classified in 2005 as “Vulnerable” by IUCN and as in “Gradual Decline” under the New Zealand Threat Classification System, and are listed in CITES (Appendix II). Basking shark has been a protected species in New Zealand since 2010.

Basking sharks are caught occasionally in hoki trawls (Francis & Duffy 2002, Francis & Smith 2010, Ballara et al 2010). Standardised capture rates from observer data showed that the highest rates and catches occurred in 1989 off the WCSI, and in 1987–92 off the ECSI. Smaller peaks in both areas were observed in the late 1990s and early 2000s, but captures have been few since (Table 12). Most basking sharks have been captured in spring and summer and nearly all came from FMAs 3, 5, 6 and 7. Much of the recent decline in basking shark captures is probably attributable to a decline in fishing effort (Francis & Smith 2010). Of a range of fisheries and environmental factors considered, vessel nationality stood out as a key factor in high catches in the late 1980s and early 1990s (Francis & Sutton, 2012). Research to improve the understanding of the interactions between basking sharks and fisheries was reported in Francis & Sutton (2012).

5.4 Benthic interactions

The only target method of capture in the hoki fishery is trawling using either bottom (demersal) or midwater gear. Baird & Wood (2010) estimated that trawling for hoki accounted for 20–40% of all tows on or near the sea floor reported on TCEPR forms up to 2005–06, and Black et al (2013) estimated that hoki has accounted for 30% of all tows reported on TCEPR forms since 1989–90. Between 2006–07 and 2010–11, 93% of hoki catch was reported on TCEPR forms. In the early years of the hoki fishery, vessels predominantly used midwater trawls as most of the catch was taken from spawning aggregations off the WCSI. Outside of the spawning season, bottom trawling is used on the Chatham Rise and Sub-Antarctic fishing grounds (Table 13). Twin trawls were used to catch almost half of the TACC in some years. This gear is substantially wider than single trawl gear and catches more fish per tow than single trawl gear. The relationship between total catch and bottom impact of twin trawls has, however, not been analysed. As the incidence of year round fishing increased, vessels increased fishing effort on the Chatham Rise and in the Sub-Antarctic, and the bottom trawl effort increased to a peak between 1997–98 and 2003–04. Effort has declined substantially in all areas since 2005–06, largely as a result of TACC reductions but is now likely to increase again with increases in TACCs in recent years. Midwater trawling peaked in 1995–96 to 1996–97 in Cook Strait and on the Chatham Rise 1996–97 to 1997–98, but declined in all areas from 1997–98. Overall, midwater trawling has declined by about 90% since the peak in 1997 and bottom trawling by about 70% since the peak in 2000 (Table 13).

Table 12: Number of tows (data version 20140131), and number of captures (1994–95 to 2007–08 from Francis & Smith 2010; 2008–09 to 2011–12 from the Central Observer Database) of basking shark in hoki trawls. Data for 2012–13 is provisional and is from v20140131.

Note: Spawning fisheries include WCSI (Jul–Sep), Cook Strait (Jul–Sep), Puysegur (Jul–Dec), ECSI (Jul–Sep). Non-spawning fisheries include ECSI (Aug–Jun), Chatham Rise (Aug–Jun), Sub-Antarctic (Aug–Jun). TCER, CELR and North Island tows are excluded.

Bottom trawling for hoki, like trawling for other species, is likely to have effects on benthic community structure and function (e.g., Rice 2006) and there may be consequences for benthic productivity (e.g., Jennings et al 2001, Hermesen et al 2003, Hiddink et al 2006, Reiss et al 2009). These are not considered in detail here but are discussed in the Aquatic Environment and Biodiversity Annual Review 2017 (MPI 2017).

5.5 Other factors

5.5.1 Spawning disruption

Fishing during spawning may disrupt spawning activity or success. Although there has been no research on the disruption of spawning hoki by fishing in New Zealand, the hoki quota owners voluntarily ceased

fishing some defined spawning grounds for certain periods on the WCSI, Pegasus Canyon (ECSI) and Cook Strait as a precautionary measure from 2004 to 2009 with the intention of assisting stock rebuilding. This closure was lifted in 2010 because the biomass of the western stock was estimated to have rebuilt to within the management target range.

5.5.2 Habitat of particular significance to fisheries management

Habitats of particular significance to fisheries management have not been defined for hoki or any other New Zealand fish. Studies of potential relevance have identified areas of importance for spawning and juveniles (O'Driscoll et al 2003). Areas on Puysegur Bank, Canterbury Bight, Mernoo Bank, and Cook Strait have been subject to non-regulatory measures to reduce fishing mortality on juvenile hoki (Deepwater Group 2011).

6. STOCK ASSESSMENT

A stock assessment update was carried out in 2018 using research time series of abundance indices (trawl and acoustic surveys), proportions at age data from the commercial fisheries and trawl surveys, and estimates of biological parameters. This updated the 2017 base and sensitivity cases with new data. No additional sensitivities were considered. New information included a trawl survey, an acoustic survey, and updated catch at age data. The general-purpose stock assessment programme, CASAL (Bull et al 2012), was used to perform a Bayesian stock assessment that was an update of the 2017 assessment (McKenzie 2018a).

6.1 Methods

Model structure

The model partitioned the population into two sexes, 17 age groups (1 to 16 and a plus group, 17+), two stocks [east (E) and west (W)], and four areas [Chatham Rise (CR), West Coast South Island (WC), Sub-Antarctic (SA), and Cook Strait (CS)]. It is assumed that the adult fish of the two stocks do not mix: those from the W stock spawn off the WC and spend the rest of the year in SA; the E fish move between their spawning ground, CS, and their home ground, CR. Juvenile fish from both stocks live in CR, but natal fidelity is assumed for most model runs (i.e., all fish spawn in the area in which they were spawned). Sensitivity model runs were done in which natal fidelity is not assumed (but all fish once they have spawned in a given area return there for future spawnings; i.e., adult fidelity). There is little direct evidence of natal fidelity for hoki, though its life history characteristics would indicate that 100% natal fidelity is unlikely (Horn 2011).

The model does not distinguish between mature and immature fish; rather than having a maturity ogive and a single proportion spawning (assumed to be the same for all ages) there is simply a spawning ogive. The reason for this is that there are no direct observations of maturity to use in the model but information about proportion spawning is available (there are two April/May observations on SA of proportions of females that will spawn that year).

The model's annual cycle divides the fishing year into five time steps and includes four types of migration (Table 14). The first type of migration involves only newly spawned fish, all of which are assumed to move from the spawning grounds (CS and WC) to arrive at CR at time step 2 and approximate age 1.6 y. The second affects only young W fish, some of which are assumed to migrate, at time step 3, from CR to SA. The last two types of migrations relate to spawning. Each year some fish migrate from their home ground (CR for E fish, SA for W fish) to their spawning ground (CS for E fish, WC for W fish) at time step 4. At time step 1 in the following year all spawners return to their home grounds. Both non-spawning fisheries (on CR and SA) are split into two halves to allow some of the catch to be taken before the Whome migration, and some after (and given the labels in the model of Ensp1, Ensp2, Wnsp1, Wnsp2).

Table 14: Annual cycle of the assessment model, showing the processes taking place at each time step, their sequence within each time step, and the available observations (excluding catch-at-age). Any fishing and natural mortality within a time step occurred after all other processes, with half of the natural mortality occurring before and after the fishing mortality. An age fraction of, say, 0.25 for a time step means that a 2+ fish was treated as being of age 2.25 in that time step. etc. The last column (“Prop. mort.”) shows the proportion of that time step’s total mortality that was assumed to have taken place when each observation is made.

Step	Approx. months	Processes	<i>M</i> fraction	Age fraction	Label	Observations Prop. Mort.
1	Oct–Nov	migrations Wreturn: WC->SA, Ereturn: CS->CR	0.17	0.25	-	
2	Dec–Mar	recruitment at age 1+ to CR (for both stocks) part1, non-spawning fisheries (Ensp1, Wnsp1)	0.33	0.6	SAsumbio CRsumbio	0.5 0.6
3	Apr–Jun	migration Whome: CR->SA part2, non-spawning fisheries (Ensp2, Wnsp2)	0.25	0.9	SAautbio pspawn	0.1
4	End Jun	migrations Wspmg: SA->WC, Espmg: CR->CS	0	0.9		
5	Jul–Sep	increment ages spawning fisheries (Esp, Wsp)	0.25	0	CSacous WCacous	0.5 0.5

Data and error assumptions

Five series of abundance indices were used in the assessment (Table 15). New data were available from a trawl survey on the Chatham Rise in January 2018 (O’Driscoll & Ballara 2018) and a winter 2017 acoustic survey in Cook Strait (O’Driscoll & Escobar-Flores 2018). The age data used in the assessment (Table 15) were similar to those used in 2017, but with an additional year’s data.

The error distributions assumed were multinomial (Bull et al 2012) for the at-age data, and lognormal for all other data. The weight assigned to each data set was controlled by the effective sample size for each observation, calculated from the observation error, and a reweighting procedure for the data sets (McKenzie 2015a, Francis 2011). An arbitrary CV of 0.25 (as used by Cordue 2001) was assumed for the proportion spawning observations.

Two alternative sets of CVs were used for the biomass indices. The “total” CVs represent an estimate of the total uncertainty associated with these data, and were used in initial model runs. For the trawl-survey indices, these were calculated as the sum of an observation-error CV (which was calculated using the standard formulae for stratified random surveys; e.g., Livingston & Stevens (2002) and a process-error CV, which was set at 0.2, following Francis et al (2001) (note that CVs are added as squares: $CV_{total}^2 = CV_{process}^2 + CV_{observation}^2$). For final model runs the process-error CV for the Chatham Rise and Sub-Antarctic trawl surveys were estimated in the MPD model run, and set at their MPD estimated values for the MCMC model runs (base case: 0.144 for Chatham Rise and 0.386 for Sub-Antarctic). The base case CVs are shown in Table 17.

For the acoustic indices, the total CVs were calculated using a simulation procedure intended to include all sources of uncertainty (O'Driscoll 2002). The observation-error CVs were calculated using standard formulae for stratified random acoustic surveys (e.g., Coombs & Cordue 1995) and included only the uncertainty associated with between-transect (and within-stratum) variation in total backscatter.

Table 17: Coefficients of variation (CVs) used with biomass indices in the assessment. Total CVs include both observation error CVs and process error CVs. Process errors for CRsumbio and SAsumbio are estimated for each model in an MPD run, with total CVs shown here for the base model (1.1). Years are fishing years (1990 = 1989–90).

The observation CVs for the otolith-based, at-age data were calculated by a bootstrap procedure, which included an explicit allowance for age estimation error. No observation-error CVs were available for the OLF-based data from the non-spawning fisheries, so an ad-hoc procedure was used to derive

observation-errors, which were forced to be higher than those from the spawning fisheries (Francis 2004b). The age ranges used in the model varied amongst data sets (Table 18). In all cases, the last age for these data sets was treated as a plus group.

Table 18: Age ranges used for at-age data sets.

Data set	Age range	
	Lower	Upper
Espage, Wspage, SAsumage, SAautage	2	15+
Wnspage	2	13+
CRsumage, Enspage	1	13+
WnspOLF	2	6+
EnspOLF	1	6+
pspawn	3	9+

The catch for each year was divided among the six fisheries in the model according to area and month (Table 19). This division was done using TCEPR, TCER, CELR, NCELR, LTCER, LCER and TLCER data, and the resulting values were then scaled up to sum to the HOK 1 MHR total. The method of dividing the catches (Table 19) was the same as that used in the 2017 assessment, so the catches used in the model (Table 20) are unchanged, except for revisions to the assumed catch for 2017.

Table 19: The division of annual catches by area and months into the six model fisheries (Esp, Wsp, Ensp1, Ensp2, Wnsp1, and Wnsp1). The small amount of catch reported in the areas west coast North Island and Challenger, typically about 100 t per year, has been distributed pro-rata across all fisheries).

Fishery	Model fishery	Areas	Months
Western spawning fishery	Wsp	West Coast South Island & Puysegur	October–September
Western non-spawning fishery 1	Wnsp 1	Sub-Antarctic	October–March
Western non-spawning fishery 2	Wnsp 2	Sub-Antarctic	April–September
Eastern spawning fishery	Esp	Cook Strait & Pegasus Canyon	June–September
Eastern non-spawning fishery 1	Ensp 1	Cook Strait & Pegasus Canyon Chatham Rise, East Coast South Island, East Coast North Island & null ¹	October–March
Eastern non-spawning fishery 2	Ensp 2	Cook Strait & Pegasus Canyon	April–May
		Chatham Rise East Coast South Island East Coast North Island null ¹	April–September

¹ catch reported to no area.

For the 2017–18 year, the TACC was 150 000 t with a catch limit arrangement for 60 000 t to be taken from the eastern fisheries and 90 000 t from the western fisheries. Industry representatives indicated that the total catch taken for 2017–18 would be likely to equal the TACC with 62 000 taken from the eastern fisheries and 88 000 t from the western fisheries. In the stock assessment model the non-spawning fisheries were split into two parts, separated by the migration of fish from the Chatham Rise to the Sub-Antarctic (Table 20).

Further assumptions

Two key outputs from the assessment are B_0 - the average spawning stock biomass that would have occurred, over the period of the fishery, had there been no fishing - and the time series of year-class strengths (YCSs). For example, the YCS for 1970, was for fish spawned in the winter of 1970, that first arrived in the model in area CR, at age 1.6 y, in about December 1971, which was in model year 1972. Associated with B_0 was an estimated mean recruitment, R_0 , which was used, together with a Beverton-Holt stock-recruit function and the YCSs, to calculate the recruitment in each year. The first five YCSs (for years 1970 to 1974) were set equal to 1 (because of the lack of at-age data for the early years), but all remaining YCSs (for 1975 to 2016) were estimated, with an equality constraint for the 2015 east and west YCSs (due to insufficient information to estimate the east and west YCSs separately). The model corrects for bias in estimated YCSs arising from ageing error. YCSs were constrained to average to 1 over the years 1975 to 2013, so that R_0 may be thought of as the average recruitment over that period. R_0 and a set of YCSs were estimated separately for each stock. The B_0 for each stock was calculated as the spawning biomass that would occur given no fishing and constant recruitment, R_0 , and the initial biomass before fishing (B_{INT}) was set equal to B_0 . The steepness of the stock-recruitment relationship was assumed fixed at 0.75 (Francis 2009).

HOKI (HOK)

Two alternative approaches were used in modelling natural mortality. In most model runs it was assumed to vary with age (following a double-exponential curve) and separately for each sex; in one model run (where sex is ignored) it was assumed to be independent of age.

The model used six selectivity ogives (four for the eastern and western spawning and non-spawning fisheries and one each for the trawl surveys in areas CR and SA) and three migration ogives (Whome, Espmg, and Wspm).

Assumed maximum exploitation rates were as agreed by the Working Group in 2004: 0.5 and 0.67 for the non-spawning and spawning fisheries, respectively. Because the non-spawning fisheries were split into two approximately equal halves, a maximum exploitation rate of 0.3 was assumed for each half. This was approximately equivalent to 0.5 for the two halves combined. Penalty functions were used to discourage model fits which exceeded these maxima.

Prior distributions were assumed for all parameters (Table 21). In addition, bounds were imposed for parameters with non-uniform distributions. For the catchability parameters, these were calculated by O'Driscoll et al (2002, 2016) (who called them overall bounds); for other parameters, they were set at the 0.001 and 0.999 quantiles of their distributions. Prior distributions for all other parameters were assumed to be uniform, with bounds that were either natural (e.g., 0.1 for proportion migrating at age), wide enough so as not to affect point estimation, or, for some ogive parameters, deliberately set to constrain the ogive to a plausible shape.

Table 20: Catches (t) by fishery and fishing year (1972 means fishing year 1971–72), as used in this assessment. Years are fishing years (1990 = 1989–90). The 2018 catch is assumed based on industry advice.

Year	Ensp1	Ensp2	Wnsp1	Wnsp2	Esp	Wsp	Fishery Total

natural_mortality.all ²	M	lognormal	0.298	0.153	Smith (2004)
natural_mortality ³	M_{male} & M_{female} , ages 5–9 only	lognormal	0.182	0.509	Cordue (2006)

¹ This is a beta distribution, transformed to have its range from 0.1 to 0.6, rather than the usual 0 to 1.

² Used only in runs where M was independent of age and sex

³ Used only in runs where M varied with age and sex

Calculation of fishing intensity and B_{MSY}

The fishing intensity for a given stock and model run was calculated as an annual exploitation rate,

$$U_y = \max_{as} \left(\sum_f C_{asfy} / N_{asy} \right)$$

where the subscripts a , s , f , and y index age, sex, fishery, and year, respectively, C is the catch in numbers, and N is the number of fish in the population immediately before the first fishery of the year. This measure is deemed to be more useful than the spawning fisheries exploitation rates that have been presented in previous assessments, because it does not ignore the effect of the non-spawning fisheries, and thus represents the total fishing intensity for each stock.

For a given stock and run, the reference fishing intensities, $U_{35\%B_0}$ and $U_{50\%B_0}$, are defined as the levels of U that would cause the spawning biomass for that stock to tend to 35% B_0 or 50% B_0 , respectively, assuming deterministic recruitment and individual fishery exploitation rates that are multiples of those in the current year. These reference fishing intensities were calculated by simulating fishing using a harvest strategy in which the exploitation rate for fishery f was $mU_{f,\text{current}}$, where $U_{f,\text{current}}$ is the estimated exploitation rate for that fishery in the current year, and m is some multiplier (the same for all fisheries). For each of a series of values of m , simulations were carried out with this harvest strategy and deterministic recruitment, with each simulation continuing until the population reached equilibrium. For a given stock, $U_{x\%B_0}$ was set equal to $m_x\% U_{\text{current}}$, where the multiplier, $m_x\%$ (calculated by interpolation) was that which caused the equilibrium biomass of that stock to be $x\%B_0$.

The same sets of simulations were used to calculate B_{MSY} for each stock for the final model runs. B_{MSY} was defined as the equilibrium biomass (expressed as % B_0) for the value of m which maximised the equilibrium catch from that stock.

Calculations of fishing intensity and B_{MSY} were done for each sample from the MCMC, and results summarised as medians and credible intervals. The reference fishing intensities, $U_{35\%B_0}$ and $U_{50\%B_0}$ were summarised as medians.

Caution about the interpretation of B_{MSY} estimates

There are several reasons why B_{MSY} , as calculated in this way, is not a suitable target for management of the hoki fishery. First, it assumes a harvest strategy that is unrealistic in that it involves perfect knowledge (current biomass must be known exactly in order to calculate the target catch) and annual changes in TACC (which are unlikely to happen in New Zealand and not desirable for most stakeholders). Second, it assumes perfect knowledge of the stock-recruit relationship, which is actually very poorly known (Francis 2009). Third, the closeness of B_{MSY} to the soft limit permits the limit to be breached too easily and too frequently, given, for example, a limited period of low recruitment. Fourth,

it would be very difficult with such a low biomass target to avoid the biomass occasionally falling below 20% B_0 , the default soft limit according to the Harvest Strategy Standard.

6.2 Results

The assessment update was conducted in two steps. First, a set of initial model runs was carried out generating point estimates (so-called MPD runs, which estimate the Mode of the Posterior Distribution). Their purpose was to update final model runs from the previous assessment, and compare to these before carrying them forward as final runs. The final runs were fully Bayesian, producing posterior distributions for all quantities of interest.

An initial set of analyses was carried out after the new data became available (McKenzie 2018b). A model run with 0.2 process error assumed for the Chatham Rise and Sub-Antarctic trawl survey series, and a single catchability (q), did not fit the most recent Sub-Antarctic biomass estimates very well and the residuals from this run were unacceptable. To give acceptable residual patterns for the Chatham Rise and Sub-Antarctic trawl survey series, a run was conducted in which the process error for these were estimated (instead of being fixed at the value of 0.20). This run resulted in a lower process error for the Chatham Rise surveys (0.144) but a higher process error for the Sub-Antarctic trawl survey series (0.386). The impact of the higher process error is to increase the uncertainty in the biomass estimates for the western stock. The DWWG agreed that this run would be the base case for 2018.

The SAsumbio survey data shows large annual changes in numbers-at-age that cannot be explained entirely by changes in abundance, and which are suggestive of changes in survey catchability. Because of this, and to improve the fit to the SAsumbio series, model runs have previously been conducted where the catchability has changed over time (two q values were fitted to the survey time series). In the previous assessment, and in 2017, one catchability was assumed for the whole time series but a higher process error was allowed to account for the annual variation in observations; this effectively down weights the Sub-Antarctic trawl survey data relative to other data sources in the model.

For the previous assessment (2017) base model run, the problem of the lack of old fish in both fishery-based and survey-based observations was dealt with by allowing M (natural mortality) to be dependent on age. Also, natal fidelity was assumed, and the weighting of CRsumbio and SAsumbio trawl data determined by their estimated process error. In the base model of the 2018 assessment, these model features were kept and the model updated with the new data. The model with process error estimated (1.1) was preferred to that with process error fixed at 0.20 (Run 1.2) because of the lower residuals for the fits to CRsumbio and SAsumbio. In both models a run of four low biomass estimates from SAsumbio for 2004–2007 is not unexpected statistically (Cordue 2014). In the base case model (Run 1.1) the observation of low biomass in the November–December 2014 and November–December 2016 Sub-Antarctic trawl surveys was interpreted as being due to observation error (i.e. the survey underestimated the biomass by chance).

Sensitivity model runs were carried out to the base model run (Table 22). These tested the sensitivity of model 1.1 to the process errors for CRsumbio and SAsumbio (1.2), and the western stock biomass indices (1.3 and 1.4). Other sensitivity runs conducted included assumptions about natal fidelity but still assuming adult fidelity, and domed spawning selectivity.

Table 22: Characteristics for model runs, including sensitivities to the base run 1.1.

Run	Main assumptions
1.1 - base case	natal fidelity M is age-dependent single q for Sub-Antarctic trawl series process error of CRsumbio and SAsumbio estimated
1.2	as 1.1 but process error fixed at 0.20 for CRsumbio and SAsumbio
1.3	as 1.1 but drop SAsumbio
1.4	as 1.1 but drop WCacous

Bayesian posterior distributions were estimated for each of these runs using a Markov Chain Monte Carlo (MCMC) approach. For each run, three chains of length four million were completed, with adaptive step size allowed during the first 100 000 samples. The initial 500 000 samples of each chain was discarded, and the remaining samples were concatenated and thinned to produce a posterior sample of size 2000.

Model estimates are presented for the spawning stock biomass (Table 23), biomass trajectories and year-class strengths (Figure 3), and current biomass distributions (Figure 4). Compared to the base case (1.1), a process error of 0.20 resulted in essentially the same current biomass for the E stock ($%B_0$), whereas for the W stock the $%B_0$ was lower (Run 1.2). Dropping *SAsumbio* or *WCacous* resulted in essentially the same current biomass for the E stock ($%B_0$), whereas for the W stock the $%B_0$ was higher or lower respectively (Runs 1.3 and 1.4). Other sensitivity runs conducted included assumptions about natal fidelity but still assuming adult fidelity, and domed spawning selectivity. These are not reported here. For these other sensitivity runs median values of current biomass ($%B_0$) were greater than the upper target zone value of 50% B_0 for both stocks, except for the eastern stock of the no natal fidelity run where current biomass was estimated to be 45% B_0 , and was within the management target range

Table 23: Estimates of spawning biomass for the base case and sensitivities (median of marginal posteriors, with 95% confidence intervals in parentheses). $B_{current}$ is the spawning biomass in mid-season 2017–18. The base case 1.1 estimates the process error for *CRsumbio* and *SAsumbio*, whereas run 1.2 sets these at 0.20. All other sensitivities are conducted against the base case 1.1– see Table 22.

Run	B_0 ('000 t)		$B_{current}$ ('000 t)		$B_{current}(\%B_0)$		
	E	W	E	W	E	W	E+W
1.1 (Base)	543(438,682)	1036(822,1448)	293(193,458)	659(378,1187)	54(39,77)	64(44,86)	61(48,76)
1.2	525(425,661)	922(764,1192)	277(173,441)	483(276,829)	53(37,73)	52(34,73)	53(40,68)
1.3	563(456,729)	1449(1010,2228)	320(205,530)	1234(683,2170)	57(40,83)	84(61,110)	76(59,96)
1.4	540(438,671)	941(781,1211)	288(188,440)	527(291,883)	53(38,73)	56(35,78)	55(42,70)

Figure 3 [upper]: Estimated spawning biomass trajectories (SSB, upper panels) for the E (left panels), W (middle panels) and E + W stocks (right panels) from the base case run 1.1. Plotted values are medians (solid black line) with 95% confidence intervals (dotted lines). Years are fishing years (1990 = 1989–90). The shaded green region represents the target zone of 35–50% B_0 .

Figure 3 [Lower]: Year-class strengths (YCS, lower panels) for the E (left panels), W (middle panels) and E + W stocks (right panels) from the base case run 1.1. Plotted values are medians of marginal posterior distributions. Years are fishing years (1990 = 1989–90).

Figure 4: Estimated posterior distributions of current (spawning) biomass ($B_{2016-17}$) expressed as $\%B_0$ for the E (left panel), W (middle panel), and E + W (right panel) from the base case run 1.1. The shaded green region represents the target zone of 35–50% B_0 .

The base run (1.1) shows that the biomasses of both stocks were at their lowest points from about 2004 to 2006 (at about 28% B_0 for the E stock and 32% B_0 for the W stock) after the W stock experienced seven consecutive years of poor recruitment from 1995 to 2001 inclusive and the E stock had below average recruitment over the same period (Figure 3). Both the E and W stocks have since increased to levels which exceed the target zone. Recruitment to the W stock following the 1995–2001 period of poor recruitment was estimated to have been just below average for 2002–2009, below average in 2010 and 2012 and 2013, and well above average in 2011 and 2014 and 2015.

In the 2017 assessment base case there was a 0.99 probability that the western stock was above 35% B_0 , whereas the probability for the 2018 base case (1.1.) is 1.00. Based on the 2018 assessment, the Harvest Strategy Standard defines the western stock to have been fully rebuilt (i.e. at least a 70% probability of being above the lower bound of the management target of 35% B_0) from 2008.

Fishing intensity on both stocks was estimated to be at or near all-time highs in about 2003 and is now substantially lower (Figure 5). For the base run (1.1) estimates of deterministic B_{MSY} were 26.9% (25.3–28.2) for the E stock and 27.0% (25.8–28.0) for the W stock, with 95% confidence intervals shown in brackets.

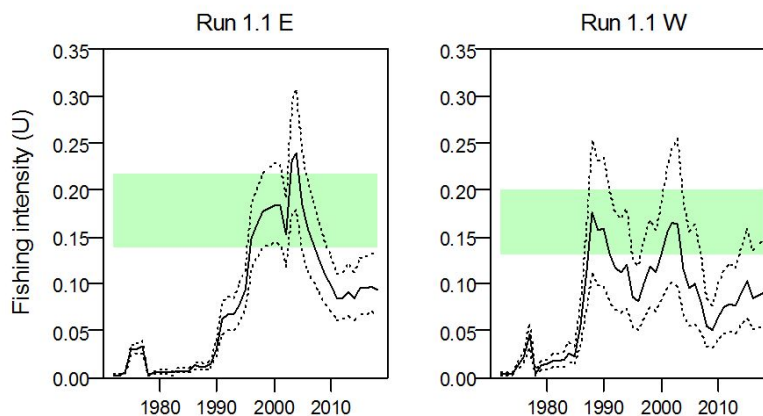

Figure 5: Base case fishing intensity, U (from MCMCs), plotted by stock. Shown are medians (solid black line) with 95% confidence intervals (dotted lines). Also shown shaded in green is the management range where the upper bound is the reference level $U_{35\%B_0}$ and the lower bound $U_{50\%B_0}$ which are the fishing intensities that would cause the spawning biomass to tend to 35% B_0 and 50% B_0 , respectively.

6.3 Projections

Five-year projections were carried out for the base model (1.1) and the most pessimistic model for the western stock (1.4), by selecting future recruitments at random from those estimated for 2007–2016. Total catch was assumed to equal the current TACC of 150 000 t with 62 000 t catch for the east stock and 88 000 t for the west stock. The projections indicate that the E and W biomasses are likely to increase over the next 5 years (Figure 6).

The estimated probability of either stock being less than the soft or the hard limit at the end of the five year projection period is negligible (Table 24). Both stocks are projected to remain within or above the 35–50% B_0 target range at the end of the projection period.

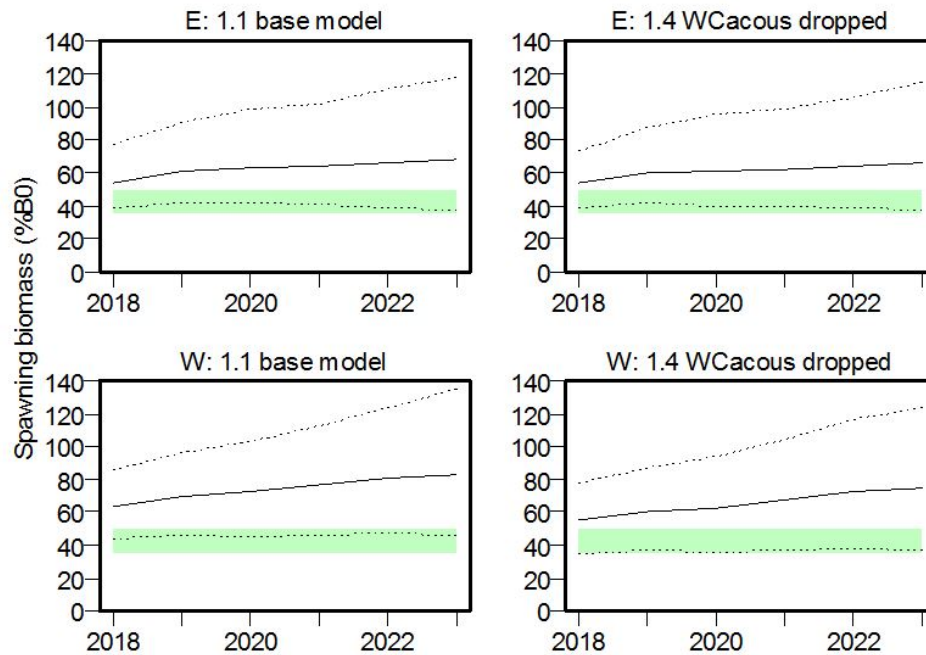

Figure 6: Projected spawning biomass (as % B_0): median (solid lines) and 95% confidence intervals (broken lines) for the base case (1.1) and a sensitivity with the west coast South Island acoustic biomass series dropped (1.17). The shaded green region represents the target management range of 35–50% B_0 .

Table 24: Probabilities (to two decimal places) associated with projections for SSB (% B_0) for the base case (1.1) for 2018 through to 2023, and for a sensitivity with the west coast South Island acoustic biomass series dropped (1.4).

7. STATUS OF THE STOCKS

Stock Structure Assumptions

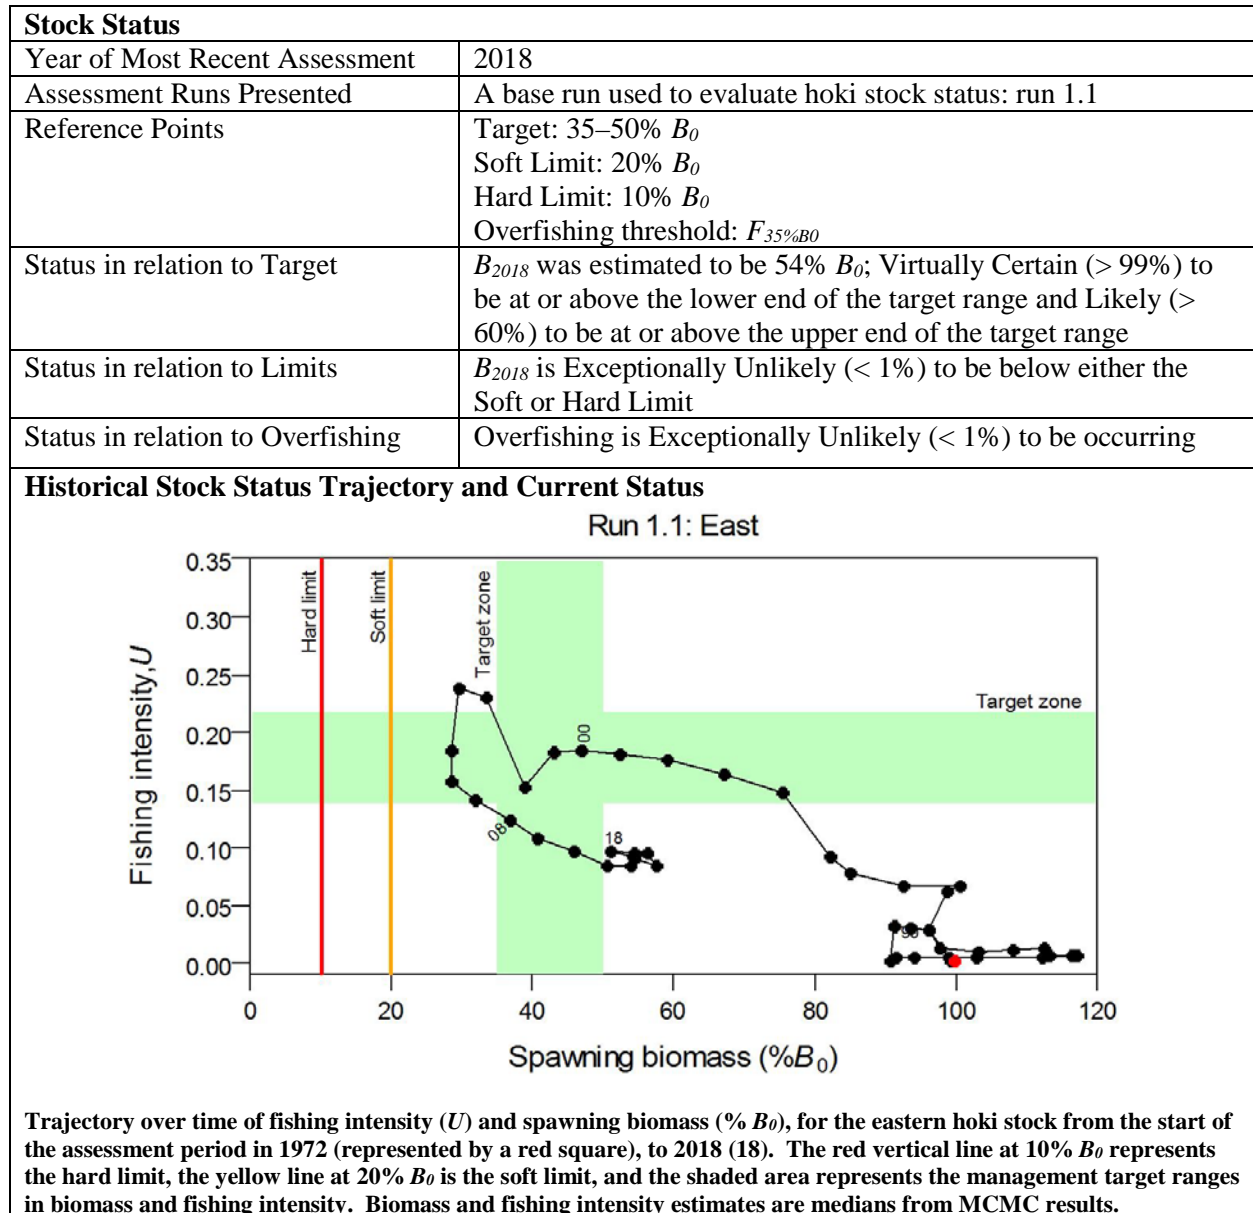

Hoki are assessed as two intermixing biological stocks, based on the presence of two main areas where simultaneously spawning takes place (Cook Strait and the WCSI), and observed and inferred migration patterns of adults and juveniles:

HOKI (HOK)

- Adults of the western stock occur on the west coast of the North and South Islands and the area south of New Zealand including Puysegur, Snares and the Sub-Antarctic;
- Adults of the eastern stock occur on the east coast of the South Island, Cook Strait and the ECNI up to North Cape;
- Juveniles of both biological stocks occur on the Chatham Rise including Mernoo Bank.

Both of these biological stocks lie within the HOK 1 Fishstock boundaries.

• Eastern Hoki Stock

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	The 2018 base case suggests that biomass has been increasing or stable for the last 7 years.
Recent Trend in Fishing Intensity or Proxy	Fishing intensity has increased slightly over the last 8 years.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	Trawl surveys of the Chatham Rise in 2016 and 2018 suggested that the three most recent year classes (2014—2016) are above average. The actual split of recruitment between the eastern and western stocks for the three most recent year classes is uncertain.

Projections and Prognosis	
Stock Projections or Prognosis	If the year classes recruit to the eastern stock as estimated by the model, the biomass of the eastern hoki stock is expected to increase over the next five years at assumed future catch levels.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Exceptionally Unlikely (< 1%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2018	Next assessment: 2019
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Research time series of abundance indices (trawl and acoustic surveys) - Proportions at age data from the commercial fisheries and trawl surveys - Estimates of fixed biological parameters	1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	- Commercial CPUE	3 – Low Quality: does not track stock biomass
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- Stock structure and migration patterns - Split of 2014, 2015, and 2016 year classes between eastern and western stocks with respect to projections	

Qualifying Comments
The Cook Strait survey estimate was lower by 50% in 2017 from 2015, and the Chatham Rise trawl survey of 3++ fish was lower by 26% in 2018 from 2016. The surveys are interpreted by the model as being low due to observation and process error.

Fishery Interactions
In Cook Strait, the main bycatch species are ling and spiny dogfish while on the Chatham Rise the main bycatch species are hake, ling, silver warehou, javeleinfish, rattails and spiny dogfish, with lesser bycatches of ghost sharks, white warehou, sea perch and stargazers. Low productivity species taken in the hoki fisheries include basking sharks, deepsea skates and some other elasmobranchs. Incidental captures of protected species have been recorded for New Zealand fur seals and seabirds.

- Western Hoki Stock**

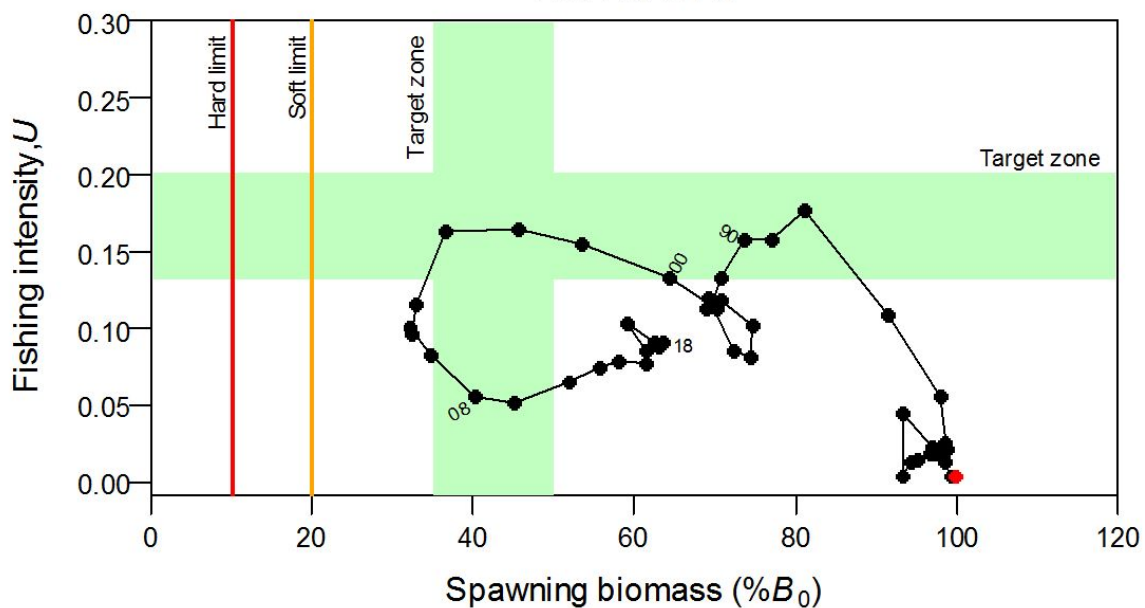

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	A base run used to evaluate hoki stock status: run 1.1
Reference Points	Target: 35–50% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{35\%B_0}$
Status in relation to Target	B_{2018} was estimated to be 64% B_0 ; Very Likely (> 90%) to be at or above the lower end of the target range and Likely (> 60%) to be at or above the upper end of the target range
Status in relation to Limits	B_{2018} is Exceptionally Unlikely (< 1%) to be below the Hard Limit and Exceptionally Unlikely (< 1%) to be below the Soft Limit

Status in relation to Overfishing

Overfishing is Very Unlikely (< 10%) to be occurring

Historical Stock Status Trajectory and Current Status

Run 1.1: West

Trajectory over time of fishing intensity (U) and spawning biomass ($\%B_0$), for the western hoki stock from the start of the assessment period in 1972 (represented by a red square), to 2018 (18). The red vertical line at $10\% B_0$ represents the hard limit, the yellow line at $20\% B_0$ is the soft limit, and the shaded area represents the management target ranges in biomass and fishing intensity. Biomass and fishing intensity estimates are medians from MCMC results.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	The 2018 base case suggests that biomass has been stable at an average of about $60\% B_0$ for the last 6 years.
Recent Trend in Fishing Intensity or Proxy	Fishing intensity has been about 0.09 for the last 5 years
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	Trawl surveys of the Chatham Rise in 2016 and 2018 suggested that the three most recent year classes (2014–2016) are above average. The actual split of recruitment between the eastern and western stocks for the three most recent year classes is uncertain.

Projections and Prognosis

Stock Projections or Prognosis	If the year classes recruit to the western stock as estimated by the model, the biomass of the western hoki stock is expected to increase over the next five years at assumed future catch levels.
Probability of Current Catch or TACC causing Biomass to remain below, or to decline below, Limits	Soft Limit: Very Unlikely (< 10%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2018	Next assessment: 2019
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Research time series of abundance indices (trawl and acoustic surveys) - Proportions at age data from the commercial fisheries and trawl surveys - Estimates of fixed biological parameters 	1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	<ul style="list-style-type: none"> - Commercial CPUE - WCSI trawl survey biomass estimate - Some years of age data, as described in Table 16 	3 – Low Quality: does not track stock biomass 3 – Low Quality: currently not included in the assessment pending an evaluation of their reliability for hoki 3- Low quality: Currently not used as it was thought not to be representative of the fishery
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Stock structure and migration patterns - Split of 2014, 2015, and 2016 year classes between eastern and western stocks with respect to projections - Possible catchability changes in Sub-Antarctic trawl surveys 	

Qualifying Comments

In the 2018 base case where process error is estimated for the two trawl surveys, there is increased uncertainty in the western stock assessment. In this run the low biomass indices from the November-December 2014 and 2016 Sub-Antarctic trawl surveys are interpreted by the model as being low due to observation and process error. The risk is that if the Sub-Antarctic trawl survey is reflecting an actual change in biomass, then the western stock status would be lower than estimated in the base case. Another trawl survey of the Sub-Antarctic is scheduled for November-December 2018.

Fishery Interactions

In the west coast South Island and Sub-Antarctic fisheries, the main bycatch species are hake, ling, silver warehou, jack mackerel and spiny dogfish. Low productivity species taken in the hoki fisheries include basking sharks, deepsea skates and some other elasmobranchs. Incidental captures of protected species have been recorded for New Zealand fur seals and seabirds.

HORSE MUSSEL (HOR)*(Atrina zelandica)*

Kukuroroa, Kupa, Hururoa

**1. FISHERY SUMMARY****1.1 Commercial fisheries**

Horse mussels (*Atrina zelandica*) were introduced into the Quota Management System on 1 April 2004, with a combined TAC of 103 t and TACC of 29 t. Customary non-commercial and recreational allowances are 9 t each, and 56 t was allowed for other sources of mortality. The fishing year is from 1 April to 31 March and commercial catches are measured in greenweight. TACCs have been allocated in HOR 1–HOR 9. Most reported landings have been from HOR 1, and apart from 1994–95 and 2002–03, when catches of about 5 and 7 t respectively were reported, reported landings have all been small (Table 1). About 90% of the catch is taken as a bycatch during bottom trawling and the remainder is taken as a bycatch of dredge and Danish seine. It is likely that there is a reasonably high level of unreported discarded horse mussel catch.

1.2 Recreational fisheries

A. zelandica do not appear in records from recreational fishing surveys (Bradford 1998), but are nevertheless taken from time to time by recreational fishers. There are no estimates of recreational take for this species.

1.3 Customary non-commercial fisheries

A traditional food of Maori, although probably underrepresented in midden shell counts because of the fragile and short-lived nature of the shell. There are no estimates of current customary non-commercial use of this species.

1.4 Illegal catch

There is no known illegal catch of this mussel.

1.5 Other sources of mortality

There is no quantitative information on other sources of mortality, although widespread die-offs appear to be characteristic of this species. Storm scour, shell damage and subsequent predation, and exceeding carrying capacity have been suggested as possible reasons for this.

HORSE MUSSEL (HOR)

Table 1: TACCs and reported landings (t) of Horse mussel by Fishstock from 1990–91 to 2016–17 from CELR and CLR data. There have never been any reported landings in HOR 4, 5, 6 or 8. These fishstocks each have a TACC of 1 t and are not reported in Table 1 below.

2. BIOLOGY

The horse (or fan) mussel, *Atrina zelandica*, is a widespread endemic bivalve that lives mainly on muddy-sand substrates in the lowest inter-tidal and sub-tidal shallows of mainly sheltered waters. Horse mussels are also found in deeper waters (to 50 m) off open coasts. The horse mussel is a flattened, emergent, filter-feeding mollusc, particularly conspicuous because of its size and abundance. Although more usually 260–300 mm long (110–120 mm wide) it can reach 400 mm in length and is New Zealand's largest bivalve. Horse mussels often live in groups, forming patches of up to 10 m² or more. The shell remains firmly embedded in the substrate by its pointed anterior end, the animal anchored to particles in the sediment by its byssus. The crenellated posterior edge projects a few centimetres above the substrate, keeping the water intake clear of surface deposits and providing attachment for an array of algae and invertebrates such as sponges and sea squirts.

Horse mussels are dioecious broadcast spawners. Although spawning may take place throughout much of the year it is probably mainly during summer. There is no information on the size or age at which breeding begins. A pelagic larva is free swimming for several days or weeks but nothing is known of its primary settlement locations, which may not necessarily be within the adult beds (some bivalves including soft sediment ones such as pipi settle in one area but later migrate to another where adult beds develop). Recruitment events can be sporadic and short-lived.

There is little published information on age, growth and mortality for horse mussels. It appears that *Atrina* grows rapidly for at least the first 2–4 years: shells about 120 mm long in a northern bed increased about 40 mm per year until 166 mm, after which growth slowed dramatically (Hay C. pers. comm. in Hayward et al 1999). Large shells are at least 5 y and possibly up to 15 y old. Widespread die-offs seem to be a feature of this species (Allan & Walshe 1984, Hayward et al 1999). For example, in the Rangitoto Channel, densities of 200–300 per m² reduced to 1–35 per m² over 2–3 y, with storm scour, shell damage and subsequent predation, and exceeding carrying capacity being possible reasons (Hayward et al 1999).

Horse mussels have widespread effects on ecosystem structure and function. They provide shelter and refuge for invertebrates and fish, and act as substrata for the settlement of epifauna such as sponges and soft corals. They also affect boundary layer dynamics, and facilitate productivity and biodiversity by depositing pseudofaeces. The horse mussel community in most northern harbours is almost entirely subtidal, in medium to fine muddy, but fairly stable, sand with moderate current velocities and no wave action. Similar communities have been observed in the Hauraki Gulf and Marlborough Sounds. Scallops, dredge oysters, and green lipped mussels are the main commercial shellfish species whose beds sometimes broadly overlap with the horse mussel.

3. STOCKS AND AREAS

For management purposes stock boundaries are based on FMAs, however, there is no biological information on stock structure, recruitment patterns, or other biological characteristics which might indicate stock boundaries.

4. STOCK ASSESSMENT

4.1 Estimates of fishery parameters and abundance

There are no estimates of fishery parameters or abundance for any horse mussel fishstock.

4.2 Biomass estimates

There are no biomass estimates for any horse mussel fishstock.

4.3 Yield estimates and projections

There are no estimates of *MCY* for any horse mussel fishstock.

There are no estimates of *CAY* for any horse mussel fishstock.

5. STATUS OF THE STOCKS

There are no estimates of reference or current biomass for any horse mussel fishstock. It is not known whether horse mussel stocks are at, above, or below a level that can produce *MSY*.

JACK MACKERELS (JMA)

(*Trachurus declivis*, *Trachurus novaezelandiae*, *Trachurus murphyi*)
Hauture

1. FISHERY SUMMARY

The jack mackerel fisheries catch three species; two New Zealand species, *Trachurus declivis* and *T. novaezelandiae*, and *T. murphyi* which appeared in New Zealand in the 1980s.

Jack mackerels have been included in the QMS since 1 October 1996, with four QMAs. Previously jack mackerels were considered part of the QMS, although ITQs were issued only in JMA 7. In JMA 1 and JMA 3, quota for the fishery was fully allocated as IQs by regulation with the exception of the 20% allocated to customary non-commercial. Before the 1995 jack mackerel regulations were issued, catch in JMA 1 taken in the Muriwhenua area north of 36° S to the limit of the Territorial Sea was not covered by the JMA 1 regulations. Allowances for customary non-commercial fishers, recreational fishers and an allowance for other sources of mortality have not yet been set.

1.1 Commercial fisheries

In JMA 1, the jack mackerel catch is largely taken by the target purse seine fishery operating in the Bay of Plenty in Statistical Area 009 during March–November, with minor catches taken as a bycatch of kahawai and blue mackerel purse seine fisheries, and as a bycatch from the trawl fishery. In most years, relatively small catches were taken from off the east Northland coast (Statistical Areas 002 and 003), although this area accounted for a substantial proportion of the total catch in 1993–94 and 1994–95.

Since 1991–92, jack mackerel targeted landings in JMA 1 have represented more than 80% of total catch. The highest rates of bycatch are from kahawai and blue mackerel targeted operations which each account for about 7% of the total jack mackerel catch. The majority of JMA 1 catch over these years has been taken from Statistical Areas 008 and 009 (Bay of Plenty) between June and November; considerably less has been taken in Statistical Areas 002 and 003, although high catches were recorded from these areas in 1993–94 and 1994–95.

In JMA 3 little targeting occurred before 1992–93. During the 1990s targeting increased and accounted for the majority of catch (about 50% between 1991–92 and 1996–97), but, after a peak of more than 80% in 1997–98 and 1998–99, has decreased again to about 50–60% in recent years. The balance of the catch in this area comes from trawl bycatch (squid 15–30%; barracouta 15–20%) on the Chatham Rise and in the Southland/Sub-Antarctic region. A purse seine fishery has operated between the Clarence River mouth and the Kaikoura Peninsula, which peaked at 4 400 t in 1992–93 and averaged more than 3 000 t between 1989–90 and 1993–94. Purse seine catches have shown a steady decline

JACK MACKERALS (JMA)

since, dropping from 1 000 t in 1994–95, to 100 t in 2001–02 and 2002–03; no catch was recorded for 2003–04, and purse seine catch has subsequently been rare.

Increased availability of jack mackerels caused by the influx of *T. murphyi* resulted in increased quotas in JMA 1 and JMA 3, to 8 000 t and 9 000 t respectively for the 1993–94 fishing year, and a further increase to 10 000 t and 18 000 t respectively for the 1994–95 year. The latter increases were made under the proviso that they be accounted for by increased catches of *T. murphyi* only; combined landings of *T. declivis* and *T. novaezelandiae* in JMA 1 and JMA 3 must not exceed the original quotas of 5 970 t and 2 700 t respectively. Industry agreed to these limits and voluntarily introduced monitoring programmes to provide the information necessary for them to be met.

For the 2016–17 fishing year, the TACC for JMA 3 was reduced to 8 780 t, approximating the 1993–94 TACC level, on the basis that recent catches had been considerably lower than the TACC and that catches of *T. murphyi* were minimal indicating low abundance of the species in New Zealand waters in recent years.

The three species occur in each of the Fishstocks, but have not been individually identified in catch records. Historical estimated and recent reported jack mackerel landings and TACCs are shown in Tables 1 and 2, while Figure 1 shows the historical landings and TACC values for the main JMA stocks. Total annual landings have ranged between 21 059 t and 50 388 t since 1986–87.

Table 1: Reported landings (t) for the main QMAs from 1931 to 1982.

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns; Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings.

Table 2: Reported landings (t) of jack mackerel by Fishstock from 1983–84 to 2016–17 and actual TACCs (t) for 1986–87 to 2016–17. QMS data from 1986–present.

* FSU data.

§ Includes landings from unknown areas before 1986–87.

‡ JMA 1 & 3 landings are totals from CLR and CELR data.tab

Landings in JMA 1 before 1989–90 were generally well below the quota of 5 970 t (Table 2), with the maximum in 1986–87 only slightly above 4 000 t. Landings increased to 7 529 t in 1992–93, followed by a substantial increase to the highest recorded value of 14 256 t in 1993–94, which was more than twice the original quota and exceeded the quota of 8 000 t set for that year. In 1994–95 reported landings (7 832 t) were half those of 1993–94. Landings from 1994–95 to 1997–98 were around 7 000 t. During 1997/98–2004/05, annual catches from JMA 1 increased to near the level of the TACC (10 000 t). Since then, annual catches have fluctuated about 8 000–10 000 t, with the exception of a considerably lower catch in 2006/07 and a peak catch of 11 200 t in 2007/08. JMA 1 landings in 2015–16 were 6 989 t, considerably less than the TACC of 10 000 t.

Estimates of the species composition of the JMA 1 purse seine catches are available from 1989–90 to 2015–16 (Figure 2). During 1989–90 and 1990–91, annual catches were dominated by *T. novaezelandiae*, but included a small component of *T. declivis*. The proportion of *T. murphyi* in the catch increased considerably over the following years, accounting for 65% of the total catch in 1993–94 and continued to account for a considerable proportion of the JMA 1 catch during 1994–95 to 1998–99. Since 1999–00, annual catches of *T. murphyi* have been minimal. From 1999–00 to 2015–16, annual catches from JMA 1 have generally been dominated by *T. novaezelandiae*. The annual catch of this species increased from about 2 000–5 000 t during the 1990s to about 8 300 t in 2007–08 to 2013–14. Correspondingly, cumulative catches of *T. declivis* and *T. murphyi* were low during this period (7% and

JACK MACKERALS (JMA)

2%, respectively). *T. novaezelandiae* annual catches from the JMA 1 purse seine fishery from 2014–15 and 2015–16 fishing years were 8858 t and 6488 t, respectively.

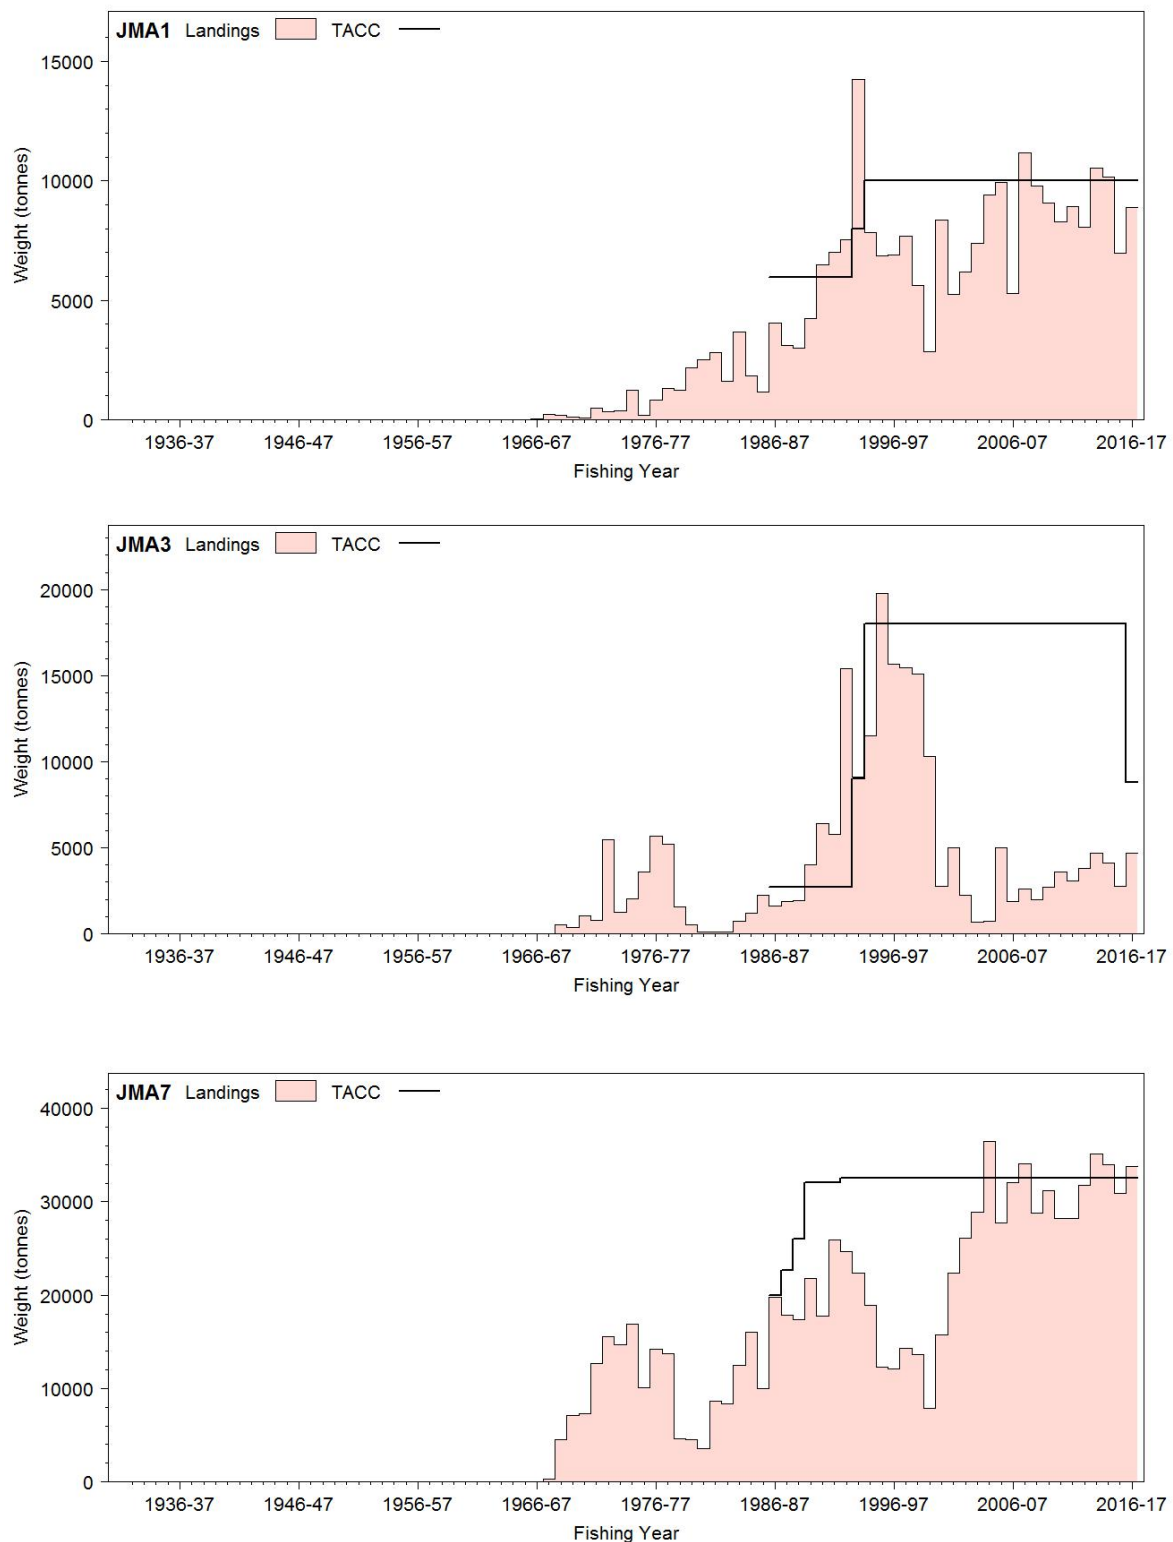

Figure 1: Reported commercial landings and TACC for the three main JMA stocks. From top: JMA 1 (Auckland East, Central East), JMA 3 (South East coast, South East Chatham Rise, Sub-Antarctic, Southland), and JMA 7 (Challenger, Central Egmont, Auckland West).

Total landings in JMA 3 over the period 1984–85 to 1988–89 were relatively constant, at a level below the quota of 2 700 t. Landings increased over subsequent years to peak in 1992–93 at almost three times that of the preceding year and more than five times the quota. Under the first of two consecutive annual increases to the JMA 3 TACC in 1993–94, landings were slightly above the limit set, but dropped well below the higher TACC level in 1994–95. The lower 1994–95 catch relative to that in 1992–93 has been attributed to the delayed implementation of the quota, less targeting of jack mackerel, and low bycatch in the squid trawl fishery. The reduced effort is thought to be a result of marketing difficulties for the relatively lower valued *T. murphyi*. Landings in JMA 3 increased markedly in 1995–96 (19 803 t) to a value exceeding the quota, with catches remaining stable around 15 500 t over three subsequent years. More recently, landings have decreased to levels well below the TACC, fluctuating between 700 t and 5 000 t since 2000–01. Declines in landings are attributed to declining abundance of *T. murphyi*, which historically comprised the bulk of JMA 3 landings. JMA 3 landings in 2016–17 were 4 665 t.

Landings in JMA 7 represent the greatest proportion of total landings and are mainly taken by chartered trawlers. Landings fluctuated between 17 403 t and 25 880 t from the mid-1980s through the mid-1990s. The marked decrease to 12 270 t in 1995–96 is attributed to changes in fishing strategies (mid-water trawling between 2 a.m. and 4 a.m. is banned under a code of practice to eliminate dolphin bycatch in JMA 7 that has been operational since 1995–96), the withdrawal of a major company from the fishery for much of the season, and difficulty marketing the relatively low valued *T. murphyi*. From 1995–96 to 1998–99, landings were in the range 12 056–14 293 t. Subsequently, landings increased steadily from 15 703 t in 2000–01 to 28 888 t in 2003–04 and to 36 507 t in 2004–05. The 2004–05 landings were 3 971 t in excess of the TACC. This increase in JMA 7 landings has been attributed to market demand and a lack of availability of preferred species quota as a result of cuts in quotas for other species and taking the lower-cost option of targeting jack mackerel instead of hoki. The 2007–08 landings were 34 059 t, about 1 500 t larger than the TACC. In 2008–09 catches decreased below the TACC by nearly 4 000 t but increased again in 2009–10 to 31 152 t, which is within 1 500 t of the quota. JMA 7 landings in 2016–17 were 33 802 t.

A number of factors have been identified that can influence landing volumes in the jack mackerel fisheries. In the purse seine fishery during the 1990s, jack mackerel was often mixed with kahawai. Fishing companies tend to avoid these mixed schools to conserve kahawai quota, particularly at the beginning of the fishing year. When mixing of the two species is prevalent, low kahawai TACC can result in the targeting of jack mackerel being inhibited. Both skipjack tuna and blue mackerel have been fished in preference to jack mackerel in the purse seine fishery with the jack mackerel season being influenced by the availability of these species. However, global increases in the market price for jack mackerel have increased its importance in the purse seine fishery to a level similar to blue mackerel, and as a result, the seasonal catch for jack mackerel has broadened considerably in recent years. This has provided fishers with a cost effective alternative to traditional purse seine targets, particularly skipjack tuna, which incurs higher costs related to on-board storage and handling.

In recent years, there has been a change in the operation of the JMA 1 purse-seine fleet. In response to market requirements, fish are no longer stored in brine on board the vessel. This has resulted in shorter trip duration and consequently a concentration of fishing effort in the Bay of Plenty in close proximity to the processing facilities in Tauranga, where *T. novaezelandiae* dominate. Market requirements for fish size also affect the jack mackerel species targeted, and consequently the areas fished.

A number of bycatch issues exist in the JMA 7 fishery. A large bycatch fishery for blue mackerel operates for many months of the year and other bycatch species taken in this fishery include barracouta, gurnard, John Dory, kingfish, and snapper. Although non-availability of ACE is unlikely to be constraining in the first three of these additional species, the same is not true of kingfish, blue mackerel, and snapper. Fishing company spokespersons have stated that known hotspots of snapper are avoided.

JACK MACKERALS (JMA)

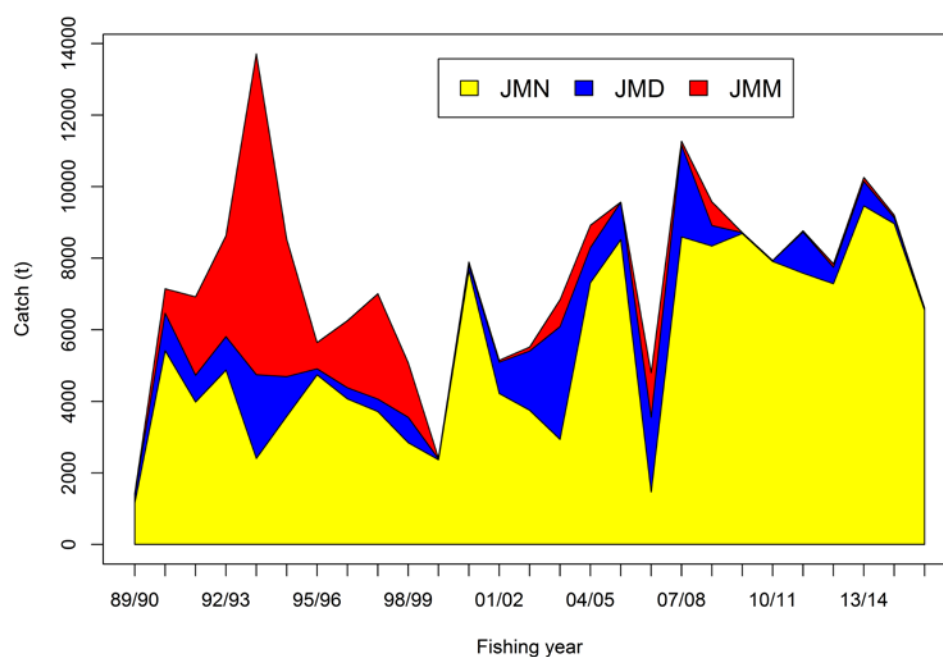

Figure 2: The time series of annual species catch estimates from the JMA 1 purse seine fishery (JMN, *T. novaezelandiae*; JMD, *T. declivis*; JMM, *T. murphyi*).

Table 3: Total JMA 1 purse seine catches and the time series of annual estimates of the species composition of the catch (JMN, *T. novaezelandiae*; JMD, *T. declivis*; JMM, *T. murphyi*) (compiled from various sources, see appendix 5 Langley et al 2016).

1.2 Recreational fisheries

Jack mackerels do not rate highly as a recreational target species although they are popular as bait.

Recreational catch in the northern region (JMA 1) was estimated at 333 000 fish (CV 0.13) by a diary survey in 1993–94 (Bradford 1996), 79 000 fish (CV 0.16) in a national recreational survey in 1996 (Bradford 1998), 349 000 fish (CV 39%) in the 2000 survey (Boyd & Reilly 2002) and 295 000 fish (CV 0.2%) in the 2001 survey (Boyd et al 2004). The surveys suggest a harvest of 80–110 t per year for JMA 1, insignificant in the context of the commercial catch. Estimates from other areas are very low (between 500 and 47 000 fish) and are insignificant in the context of the commercial catch.

The harvest estimates provided by telephone-diary surveys between 1993 and 2001 are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. In response to these problems and the cost and scale challenges associated with onsite methods, a National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Harvest estimates for jack mackerel are given in Table 4 (from Wynne-Jones et al 2014 and Hartill & Davey 2015).

Table 4: Recreational harvest estimates for jack mackerel stocks (Wynne-Jones et al 2014). Mean fish weights were obtained from boat ramp surveys; for jack mackerel the values used were 318 g for JMA 1, 339 g for JMA 3, and 511 g for JMA 7 (Hartill & Davey 2015).

Stock	Year	Method	Number of fish	Total weight (t)	CV
JMA 1	2011/12	Panel survey	101 076	32.2	0.20
JMA 3	2011/12	Panel survey	50	<1	1.01
JMA 7	2011/12	Panel survey	11 194	10.2	0.57
JMA total	2011/12	Panel survey	121 116	42.4	0.21

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

Quantitative information on the current level of Maori customary non-commercial catch is not available.

1.4 Illegal catch

There is no information on illegal activity or catch but it is considered to be insignificant.

1.5 Other sources of mortality

There is no information on other sources of mortality.

2. BIOLOGY

The three species of jack mackerel in New Zealand have different geographical distributions, but their ranges partially overlap. *T. novaezelandiae* predominates in waters shallower than 150 m and warmer than 13°C; it is uncommon south of latitude 42°S. *T. declivis* generally occurs in deeper (but less than 300 m) waters less than 16°C, north of latitude 45°S. *T. murphyi* occurs to depths of least 500 m and has a wide latitudinal range (0°S at the Galapagos Islands and coastal Ecuador, to south of 40°S off the Chilean coast).

T. murphyi was first described from New Zealand waters in 1987. Its presence was recorded off the south and east coasts of the South Island. It expanded onto the west coast of the South Island and the North and South Taranaki Bights by the late 1980s, reaching the Bay of Plenty in appreciable quantities by 1992 and becoming common on the east coast of Northland by June 1994. However, this extensive

JACK MACKERALS (JMA)

distribution has decreased in more recent years and, since the late 1990s, its presence north of Cook Strait has been sporadic with occasional landings in the JMA 1 purse seine fishery north of East Cape and from the JMA 1 inshore trawl fishery south of East Cape. The total range of *T. murphyi* extends along the west coast of South America, across the South Pacific, through to the New Zealand EEZ, and into waters off southeastern Australia.

All species can be caught by bottom trawl, mid-water trawl, or by purse seine targeting surface schools.

The vertical and horizontal movement patterns are poorly understood. Jack mackerels are presumed to be generally off the bottom at night, and surface schools can be quite common during the day.

Jack mackerels have a protracted spring-summer spawning season. *T. novaezelandiae* probably matures at about 26–30 cm fork length (FL) at an age of 3–4 years, and *T. declivis* matures when about 26–30 cm FL at an age of 2–4 years. Spawning occurs in the North and South Taranaki Bights, and probably in other areas as well.

The reproductive biology of *T. murphyi* in New Zealand waters is not well understood. Pre- and post-spawning fish have been recorded from the Chatham Rise, Stewart-Snares shelf, Northland east coast and off Kaikoura in summer, but it is unknown whether there has been any resulting recruitment in New Zealand waters. A recent study showed that older size/age groups become increasingly dominant in catches as one moves westward from the South American coast, suggesting that an eastward migration of oceanic spawned larvae and juveniles occurs in the South Pacific.

Initial ageing of *T. murphyi* taken in New Zealand waters has been completed, but the estimates are yet to be validated. Initial growth is rapid, slowing at 6–7 years, and *T. murphyi* is a moderately long-lived species with a maximum observed age of 32 years. *T. novaezelandiae* and *T. declivis* have moderate initial growth rates that slow after about 6 years. Both species reach a maximum age of 25+ years.

The best available estimate of M for *T. novaezelandiae* and *T. declivis* is 0.18 based on the age-frequency distributions of lightly exploited populations in the Bay of Plenty. Assuming $M = 0.18$, estimates of Z made in 1989 suggest that F is less than 0.05 for both endemic species off the central west coast (the main jack mackerel fishing ground). Biological parameters relevant to the stock assessment are shown in Table 5.

Table 5: Estimates of biological parameters.

Fishstock		Estimate	Source
<u>1. Natural mortality (<i>M</i>)</u>			
All		0.18

<i>T. s. murphyi</i>	51.2 cm	0.155	-1.4
			Taylor et al (2002b)

3. STOCKS AND AREAS

There is no new information that would alter the stock boundaries given in previous assessment documents. For assessment purposes the three jack mackerel species are treated separately where possible.

There are two possible hypotheses on the stock structure of *T. murphyi* in New Zealand waters: it is either a separate stock established by fish migrating from South America, or part of a single, extensive

trans-Pacific stock. While successful recruitment in New Zealand waters would indicate the establishment of a separate stock, current evidence favours the latter hypothesis with an extensive stock between latitudes 35–50° S, linking the coasts of Chile and New Zealand across what has been described as ‘the jack mackerel belt’. Few detailed data are available to document the process of range expansion by *T. murphyi* or indicate the relative abundance of the three species in particular areas. As a requirement of the increased TACCs introduced in 1994–95, improvements to jack mackerel catch monitoring were made in order to provide adequate data for quantifying species composition and the relative abundance in JMA 1 and JMA 3.

4. ENVIRONMENTAL AND ECOSYSTEM CONSIDERATIONS

This section was updated for the 2018 Fisheries Assessment Plenary based on reviews of similar chapters by the Aquatic Environment Working Group. This summary is for the jack mackerel fisheries, but a more detailed summary, issue-by-issue, is available in the Aquatic Environment & Biodiversity Annual Review 2017 (MPI 2017): <https://www.mpi.govt.nz/dmsdocument/27471-aquatic-environment-and-biodiversity-annual-review-aear-2017-a-summary-of-environmental-interactions-between-the-seafood-sector-and-the-aquatic-environment>.

4.1 Role in the ecosystem

A study of fish assemblages using research trawls suggested that *Trachurus novaezelandiae* is part of an inshore assemblage that prefers shallow northern waters (centred on about 60 m depth and latitude about 38.7° S). All three species overlap spatially, but *T. declivis* is part of a deeper assemblage around central New Zealand (centred on about 130 m and about 40.1° S), and *T. murphyi* occurs deeper still and further south (centred on about 220 m and about 44.7° S) (Francis et al 2002). *T. novaezelandiae* and *T. declivis* range through the water column from surface to the sea floor. The behaviour of *T. murphyi* in New Zealand is less well known but studies off Chile suggest that this species tends to aggregate at night and that this could reflect nocturnal foraging (Bertrand et al 2004, 2006). The effect on the ecosystem of extracting, for example, about 10 000 t of jack mackerels from JMA 1 and 30 000 t from JMA 3 per year over the past decade is unknown.

4.1.1 Trophic interactions

Stevens et al (2011) reported the diet of *T. novaezelandiae* and *T. declivis* from the Bay of Plenty, Northland and the west coast South Island to be predominantly euphausiids with fewer amphipods and fish (see also Hurst 1980). Crustaceans (several groups) were the dominant prey of *T. novaezelandiae* in the Hauraki Gulf, with fewer fish and polychaetes (Godfriaux 1968 and 1970). The diet of *T. murphyi* from research trawls on shelf areas around New Zealand, mainly down to 500 m depth, included: crustaceans (55%, mainly euphausiids 38%, amphipods 12%, and *Munida* 6%); salps (36%); and teleosts (11% percentage frequency of occurrence in stomachs with food, Stevens et al 2011).

Predators of jack mackerels are likely to include many fishes, seabirds and marine mammals given the relatively high abundance of jack mackerels. The diet of gemfish from research trawls in Southland included *Trachurus* spp. (6% of total, Stevens et al 2011). *T. declivis* and *T. murphyi* were identified from the stomachs of leafscale gulper shark and Plunket’s shark and *T. declivis* from the stomachs of school shark (Dunn et al 2010). The diet of spiny dogfish included scavenged jack mackerel (Dunn et al 2013).

4.2 Bycatch (fish and invertebrates)

Anderson (2007) used data from scientific observers and commercial catch-effort returns to estimate the rates and annual levels of fish bycatch and discards in the jack mackerel trawl fishery, from 2001–02 to 2004–05. Jack mackerel species accounted for 70% of the total estimated catch from trawls targeting jack mackerels between 1 October 2001 and 30 September 2005. The remaining 30% comprised mostly other commercial species, especially barracouta (Table 6). Although over 99% of the catch was of commercial species, altogether about 130 taxa were identified by observers. The main species discarded were spiny dogfish (only 8% of which was retained) and thresher shark (3% retained).

Between 2009 and 2011, *T. novaezelandiae* dominated 97% of purse seine landings in JMA 1 (Walsh et al 2012). The estimated proportions by year were 1–17% for *T. declivis*, 0–3% for *T. murphyi*, and

JACK MACKERALS (JMA)

81–99% for *T. novaezelandiae*. There was spatial and temporal heterogeneity in size and abundance; *T. novaezelandiae* dominated landings from the Bay of Plenty throughout the year and large *T. declivis* and *T. murphyi* were common in east Northland during winter.

Table 6: Bycatch and discards from all observer records for the target trawl fishery for jack mackerel from 1 October 2001 to 30 September 2005 for species or species groups with a total catch of 100 t or more, ordered by decreasing percentage of catch.

Species code	Common name	Scientific name	Estimated catch (t)	% of catch	% retained
JMA	Jack mackerel	<i>Trachurus declivis</i> , <i>T.m.</i> , <i>T.nz.</i>	15 978	69.53	100.0
BAR	Barracouta	<i>Thyrsites atun</i>	3 593	15.64	100.0
EMA	Blue mackerel	<i>Scomber australasicus</i>	1 093	4.76	100.0

SPD	Spiny dogfish	<i>Squalus acanthias</i>	101	0.44	8.0
-	Others	-	419	1.84	-

4.3 Incidental Capture of Protected Species (seabirds, mammals, and protected fish)

For protected species, capture estimates presented here include all animals recovered to the deck (alive, injured or dead) of fishing vessels but do not include any cryptic mortality e.g., seabirds struck by a warp but not brought onboard the vessel (Middleton & Abraham, 2007).

4.3.1 Marine mammal interactions

Jack mackerel trawlers occasionally catch marine mammals, primarily common dolphin, long-finned pilot whale, and NZ fur seal (which were all classified as “Not Threatened” under the NZ Threat Classification System in 2013, Baker et al 2016).

Between 2002–03 and 2016–17, there were 197 observed captures of whales and dolphins in jack mackerel trawl fisheries. Observed captures were common dolphin (183), long-finned pilot whale (13), and dusky dolphin (1). In the 2015–16 and 2016–17 fishing years there were 2 and 0 observed captures of common dolphins in jack mackerel trawl fisheries, respectively (Table 7). Estimated captures for 2002–03 to 2015–16 are shown in Table 7. Common dolphins were observed captured off the Taranaki coast or off the west coast of the North Island (Abraham et al 2016). Modifications to the captures estimation model are currently being evaluated via the Aquatic Environment Working Group, reflecting structural changes in fisheries operations in recent years; for this reason captures estimates are not currently available for the 2016–17 year. The fifteen year average of the rate of capture for common dolphins is 2.1 captures per 100 tows (range 0 to 11.2) in the jack mackerel fishery.

Table 7: Number of tows by fishing year and observed and model-estimated total common dolphin captures in jack mackerel trawl fisheries, 2002–03 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows, % inc, percentage of total effort included in the statistical model. Estimates are based on methods described in Abraham et al (2016) and available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 20160001.

	Tows	Observed				Estimated	
		No.ob	%ob	Capture	Rate	Captures	95%c.i.

2015–16	1 546	1 384	89.5	2	0.1	3	2–7
2016–17	1 402	1 019	72.7	0	0		

4.3.2 Seabird interactions

Annual observed seabird capture rates ranged from 0 to 1.4 per 100 tows in jack mackerel fisheries between 2002–03 and 2016–17 (Abraham & Thompson 2009, Abraham et al 2009, Abraham & Thompson 2011, Thompson et al 2013, Abraham et al 2016). Capture rates have fluctuated without obvious trend at this low level (Table 9). In the 2015–16 fishing year there were 6 observed captures of birds in the jack mackerel trawl fishery, and 4 in the 2016–17 fishing year, at a rate of 0.4 birds per 100 observed tows. Total estimated seabird captures in the jack mackerel trawl fishery varied from 7 to 26 between 2002–03 and 2015–16 (Table 9).

Table 9: Number of tows by fishing year and observed seabird captures in jack mackerel trawl fisheries, 2002–03 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows. Estimates are based on methods described in Abraham et al (2016) and Abraham & Richard (2017, 2018) and are available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 2017v1.

	Fishing effort			Observed captures		Estimated captures	
	Tows	No. Obs	% obs	Captures	Rate	Mean	95% c.i.
2002–03	3 067	346	11.3	4	1.2	22	11–39
2003–04	2 383	152	6.4	0	0	7	1–16
2004–05	2 509	558	22.2	8	1.4	17	10–27
2005–06	2 808	709	25.2	0	0	17	6–35
2006–07	2 711	802	29.6	1	0.1	8	2–17
2007–08	2 651	818	30.9	1	0.1	9	3–18
2008–09	2 168	813	37.5	6	0.7	14	7–24
2009–10	2 406	786	32.7	9	1.1	17	10–28
2010–11	1 881	594	31.6	7	1.2	16	9–30
2011–12	2 031	1548	76.2	5	0.3	9	5–16
2012–13	2 210	1937	87.6	24	1.2	26	25–29
2013–14	2 453	2193	89.4	6	0.3	7	6–12
2014–15	1 748	1513	86.6	11	0.7	14	12–21
2015–16	1 546	1384	89.5	6	0.4	7	6–12
2016–17	1 402	1019	72.7	4	0.4		

Observed seabird captures since 2002–03 have been mostly prions, shearwaters, and petrels (65 of the 95 observed seabird captures), with 25 observed albatross captures (Table 10). Seabird captures in the jack mackerel fishery have been observed mostly on the Stewart-Snares shelf, off Taranaki, and off the East Coast South Island. These numbers should be regarded as only a general guide on the distribution of captures because the numbers are small, and the observer coverage is not uniform across areas and may not be representative.

Table 10: Number of observed seabird captures in jack mackerel trawl fisheries, 2002–03 to 2016–17, by species and area. The risk category is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the Population Sustainability Threshold, PST (from Richard et al 2017, where full details of the risk assessment approach can be found). It is not an estimate of the risk posed by fishing for jack mackerel. Data based on version 2017v1.

Species	Risk Category	Taranaki	West Coast North Island	Chatham Rise	Stewart Snares Shelf	East Coast South Island	West Coast South Island	Total
Salvin's albatross	High	0	0	0	0	3	0	3
Southern Buller's albatross	High	0	0	1	3	2	0	6
New Zealand white-capped albatross	High	3	0	0	9	4	0	16
Total albatrosses	-	3	0	1	12	9	0	25
Westland petrel	High	0	0	0	0	0	1	1
White-chinned petrel	Negligible	0	0	0	25	5	0	30
Sooty shearwater	Negligible	1	0	0	6	2	0	9
Common diving petrel	Negligible	0	0	0	1	0	1	2
White-faced storm petrels	Negligible	0	3	0	0	0	0	3
Australasian gannet	Negligible	1	0	0	0	0	0	1
Fairy prion	Negligible	5	0	0	2	1	0	8
Cape petrels	-	1	0	0	0	0	1	2
Fulmar prion	-	9	0	0	0	0	0	9
Grey-backed storm petrel	-	0	0	1	0	0	0	1
Total other birds	-	16	3	1	34	8	3	65

The jack mackerel target fishery contributes to the total risk posed by New Zealand commercial fishing to seabirds (see Table 11). The species to which the fishery poses the most risk is Southern Buller's albatross, with this target fishery posing 0.002 of PST (Table 11). Southern Buller's albatross was assessed at high risk (Richard et al 2017).

Table 11: Risk ratio of seabirds predicted by the level two risk assessment for the jack mackerel and all fisheries included in the level two risk assessment, 2006–07 to 2016–17, showing seabird species with a risk ratio of at least 0.001 of PST. The risk ratio is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the Population Sustainability Threshold, PST (from Richard et al 2017, where full details of the risk assessment approach can be found). The DOC threat classifications are shown (Robertson et al 2017 at <http://www.doc.govt.nz/documents/science-and-technical/nztcs19entire.pdf>).

Species name	PST (mean)	Risk ratio		Risk category	DOC Threat Classification
		MAC risk ratio	TOTAL		
Southern Buller's albatross	1 368.4	0.002	0.392	High	At Risk: Naturally Uncommon
New Zealand white-capped albatross	10 900.3	0.001	0.353	High	At Risk: Declining

Mitigation methods such as streamer (tori) lines, Brady bird bafflers, warp deflectors, and offal management are used in the jack mackerel trawl fishery. Warp mitigation was voluntarily introduced from about 2004 and made mandatory in April 2006 (Department of Internal Affairs 2006). The 2006 Notice mandated that all trawlers over 28 m in length use a seabird scaring device while trawling ("paired streamer lines", "bird baffler" or "warp deflector" as defined in the Notice).

4.4 Benthic interactions

Jack mackerel are taken using trawls that are sometimes fished on or near the seabed. Black et al (2013) estimated that between 2006–07 and 2010–11, 78% of jack mackerel catch was reported on TCEPR forms. Target jack mackerel tows accounted for about 3.5% of all tows reported on TCEPR forms to have been fished on or close to the bottom between 1989–90 and 2004–05 (Baird et al 2011). These tows were located in Benthic Optimised Marine Environment Classification (BOMECE, Leathwick et al 2009) classes C, E (shelf), H (upper slope), and J (mid-slope) (Baird & Wood 2012), and 91% were in water shallower than 200 m (Baird et al 2011).

Trawling for jack mackerel with some or all of the gear contacting the bottom, like trawling for other species, is likely to have effects on benthic community structure and function (e.g., Rice 2006) and there may be consequences for benthic productivity (e.g., Jennings et al 2001, Hermsen et al 2003, Hiddink et al 2006, Reiss et al 2009). These consequences are not considered in detail here but are discussed in the Aquatic Environment and Biodiversity Annual Review (MPI 2016).

4.5 Other considerations

4.5.1 Spawning disruption

Fishing may disrupt spawning activity or success. Canadian research carried out on Atlantic cod (*Gadus morhua*) concluded that "Cod exposed to a chronic stressor are able to spawn successfully, but there appears to be a negative impact of this stress on their reproductive output, particularly through the production of abnormal larvae" (Morgan et al 1999). Morgan et al (1997) also reported disruption of a spawning shoal of Atlantic cod: "Following passage of the trawl, a 300-m-wide "hole" in the aggregation spanned the trawl track. Disturbance was detected for 77 min after passage of the trawl." There have been no specific studies for jack mackerel in New Zealand waters, but information on the timing and location of spawning and fishing exists. *T. declivis* and *T. novaezelandiae* are serial spawners with a protracted spring-summer spawning season (Hurst et al 2000). *T. murphyi* appears to spawn from late winter through to summer (Horn 1990, Hurst et al 2000). The JMA 7 trawl fishery has peaks of catch and effort in spring-summer (October–March) and in winter (April–September), (McKenzie, 2008), the former overlapping with spawning. Most of the purse seine catch taken from the Bay of Plenty is in September–October, but an increasing proportion has been caught in November–December since 2005–06 (Walsh et al 2012), also overlapping the spring-summer spawning.

4.5.2 Habitat of particular significance to fisheries management

Habitat of particular significance for fisheries management (HPSFM) does not have a policy definition (MPI, 2016) although work is underway to generate one. Studies of potential relevance have identified

areas of importance for spawning and juveniles (Hurst et al 2000). *T. declivis* spawning was found to be common on the southwest and northwest outer shelf North Island, and moderate to high abundance of juveniles was recorded from northwest North Island, Hauraki Gulf, and Bay of Plenty outer shelf. *T. novaezealandiae* spawning was found to be common on the southwest and northwest inner and outer shelf North Island, and moderate to high abundance of juveniles was recorded from Hauraki Gulf and Bay of Plenty inner and outer shelf, East Cape inner shelf, and Tasman/Golden Bays. *T. murphyi* spawning was found to be common on the southwest outer shelf and only low abundance of juveniles was recorded from the outer Southland shelf and 300–600 m on the Chatham Rise.

4.5.3 Genetic effects

Fishing and environmental changes, including those caused by climate change or pollution, could alter the genetic composition or diversity of a species. There are no known studies of the genetic diversity of jack mackerels in New Zealand.

4.5.4 Marine heatwave

The effects of the marine heatwave on jack mackerel fisheries that was experienced in New Zealand Waters in the summer months of 2017-18 are unknown.

5. STOCK ASSESSMENT

Stock assessments for jack mackerel are complicated by the reporting and management of three species under a single code. Preliminary stock assessments for *T. declivis* and *T. novaezealandiae* in JMA 7 were undertaken in 2007 based on data from a new Bayesian analysis for splitting the recorded commercial catch into *T. declivis*, *T. novaezealandiae*, and *T. murphyi* components. This analysis was used to derive CPUE indices and a catch history for the *T. declivis* fishery in JMA 7, which were incorporated along with a proportions-at-age series into the assessments.

The assessment for *T. declivis* is described below, but the assessment for *T. novaezealandiae* is not included because of convergence problems with the assessment model which led to its rejection by the working group.

Otherwise, there are no new data that would alter the yield estimates given in the 1996 Plenary Report. Estimates of *MCY* for JMA 1 and JMA 3 have not changed since the 1993 Plenary Report. Other yield estimates have not changed since the 1991 Plenary Report. The yield estimates are based on biomass estimates from a stock reduction analysis and aerial sightings data.

5.1 *T. declivis* in Challenger, Central West and Auckland West (JMA 7)

Species Proportion Estimates

A Bayesian species proportions model was used to estimate the proportion of *T. declivis* in the reported (TCEPR) catch for the JMA 7 fishery from 1989–90 through to 2004–05. Six spatial-temporal strata were used in the model: three spatial strata in combination with two temporal strata. The three spatial strata consisted of three regions with differing patterns in the relative proportions of the three jack mackerel species. The two temporal strata are a summer fishery (October–March) and a winter fishery (April–September). In the model the species proportions are estimated for each year (1989–90 to 2004–05), and the six strata for that year.

CPUE

The Bayesian species proportions model was used to estimate the *T. declivis* catch for each TCEPR tow, and the derived catch-effort data used in a standardised CPUE analysis. Based on changes in jack mackerel fishery practice, and changes in vessel composition over time, the CPUE analysis was split into two time periods: an early period covering the years 1989–90 to 1995–96, and a late period covering 1996–97 to 2004–05 (Table 12).

JACK MACKERALS (JMA)

Table 12: Standardised CPUE indices (relative year effects) with number of tows from 1989–90 to 2004–05.

	Year	CPUE index	CV	Number of tows
1989–90	1990	2.07	0.1	716
1990–91	1991	2.05	0.1	688
1991–92	1992	1.9	0.1	947
1992–93	1993	1.56	0.09	1 088
1993–94	1994	1.37	0.09	1 444
1994–95	1995	1.28	0.09	597
1995–96	1996	0.89	0.1	502
1996–97	1997	1.69	0.13	160
1997–98	1998	0.92	0.11	252
1998–99	1999	2.7	0.08	712
1999–00	2000	2.15	0.08	717
2000–01	2001	2.67	0.07	1 240
2001–02	2002	2.85	0.07	1 760
2002–03	2003	2.38	0.06	2 272
2003–04	2004	2.59	0.07	2 055
2004–05	2005	3.23	0.07	2 002

Catch History

Catch records for jack mackerel extend back to 1946, although landings are small until the mid-1960s. The Bayesian model annual species proportions were used to estimate the *T. declivis* landings from 1991–92 to 2004–05, while previous species proportions were used to estimate landings for the earlier years (Table 13). Recreational catch, illegal catch, and customary non-commercial catch are not well known, though are small relative to the commercial catch, so no components are included for these in the catch history.

Catch at Age

Catch-at-age data were used from the commercial fishery in the years 1989–90, 1990–91, 1995–96, and 2004–05.

Table 13: Catch history (t) for *T. declivis* in the JMA 7 fishery. The year denotes the calendar year at the end of the fishing year.

Year	Estimated catch	Year	Estimated catch	Year	Estimated catch
1946	3	1967	3 326	1988	10 340
1947	1	1968	3 326	1989	10 963
1948	2	1969	3 326	1990	6 315
1949	8	1970	2 787	1991	6 759
1950	0	1971	4 634	1992	12 422

1962	2	1983	5 540	2004	16 752
1963	5	1984	6 980	2005	17 154
1964	4	1985	8 967	2006	—
1965	3	1986	6 801	2007	—
1966	23	1987	11 493	2008	—

Model Structure

In 2007, the observational data were incorporated into an age-based Bayesian stock assessment to estimate stock size. The stock was considered to reside in a single area, with no partition by sex or maturity. In the model age groups were 1–25 years, with a plus group of 25+. The model covered the period 1965–2005 (estimated catch was insignificant before 1965).

There was a single time step in the model, in which the order of processes is ageing, recruitment, and mortality (natural and fishing). Recruitment numbers followed a Beverton-Holt relationship with steepness of 0.924 derived from a mean value over a number of species similar to jack mackerel. Maturation was not explicitly modeled; instead a maturity-at-age logistic ogive was used with an a_{50} of 3 and an a_{1095} of 9 years. Growth was assumed to follow a von Bertalanffy curve.

The model was fitted to: (a) an early CPUE series covering the years 1990 to 1996, (b) a late CPUE series covering the years 1997 through to 2005, (c) and a commercial proportions-at-age series for 1990, 1991, 1996, and 2005. A research trawl proportions-at-age for 1981 was not entered into the model, but the fit to it was evaluated outside the model assuming that the research trawl selectivity is the same as the commercial trawl selectivity. A double half normal curve was used to model the commercial trawl selectivity.

The relative influence of the different data series in the model was evaluated by dropping the early CPUE series, dropping the late CPUE series, and putting more weight on the proportions-at-age data by increasing their effective sample size.

Results

For the base model in this preliminary assessment it was estimated that current biomass is at 53% of virgin biomass (B_0). The biomass trajectory indicates a decline in biomass until the mid 1990s, followed by an increase in biomass until 2002, subsequently followed by a slight decline (Figure 3).

Dropping the early CPUE series put the estimate of current biomass at 76% B_0 , in contrast dropping the late CPUE series put the current biomass at only 30% B_0 . Doubling the effective sample sizes for all the proportions-at-age data put the estimate of current biomass at 66% B_0 .

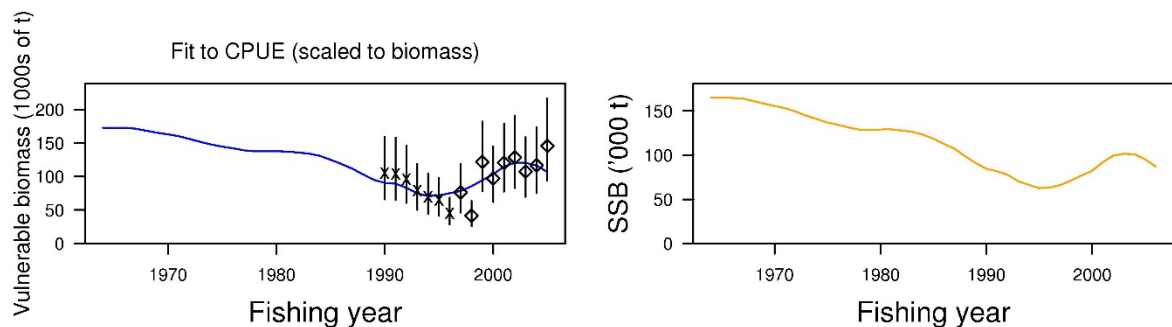

Figure 3: Biomass trajectories for the base case. The left-hand graph shows the fit of the CPUE indices to the vulnerable biomass; the right-hand graph shows the mature biomass trajectory. The year denotes the calendar year at the end of the fishing year.

5.2 Estimates of fishery parameters and abundance

Estimates of fishery parameters are given in Table 14.

Table 14: Estimates of fishery parameters.

Parameter	Fishstock	Estimate	Species	Source
$F_{0.1}$	JMA 7	0.23	<i>T. declivis</i>	Horn (1991a)
		0.33	<i>T. novaezelandiae</i>	Horn (1991a)

5.3 Biomass estimates

Biomass estimates are discussed in the section on estimation of *MCY*. Estimates of current biomass are not available.

5.4 Yield estimates and projections

The 2007 assessment for *T. declivis* did not include yield estimates so there is no information to update the historical estimates described below.

(i) Challenger, Central (West) and part of Auckland (West) (FMAs 7, 8, and part of 9)

MCY was estimated in the early 1990s for the two endemic jack mackerel species separately using the equation $MCY = 2/3 MSY$ (Method 3). The deterministic *MSY* values (8.8% and 14.7% of B_0 for *T. declivis* and *T. novaezelandiae* respectively) were calculated using a yield per recruit analysis and a Beverton and Holt stock-recruitment relationship with an assumed steepness of 0.95. B_0 was estimated using a backward projection of a stock reduction analysis that produced biomass trajectories over the period 1970–90.

For *Trachurus declivis*, $B_0 = 200\,000$ t,

$$\begin{aligned} MCY &= 2/3 \times (0.088 \times 200\,000 \text{ t}) \\ &= 11\,800 \text{ t} \end{aligned}$$

For *Trachurus novaezelandiae*, $B_0 = 100\,000$ t,

$$\begin{aligned} MCY &= 2/3 \times (0.147 \times 100\,000 \text{ t}) \\ &= 9\,800 \text{ t} \end{aligned}$$

Because these yield estimates are based on an assumed stock-recruitment relationship, they are highly uncertain.

(ii) Northland, Bay of Plenty, east coast North Island (FMAs 1 and 2)

Annual landings before 1990–91 ranged from 1 173 t to less than 5 000 t. Landings subsequently increased markedly as a result of the increased availability of *T. murphyi* to a maximum in excess of 14 000 t in 1993–94. Concerns about the assumptions used to produce the original yield estimate and the production of time series abundance indices from aerial sightings data resulted in a revised yield estimate in the mid 1990s. The aerial sightings indices showed little change in jack mackerel abundance estimates in JMA 1 between 1976 and 1990.

MCY was estimated in 1993 using the equation $MCY = cY_{AV}$ (method 4) incorporating the mean of removals from 1983–84 to 1989–90, before the *T. murphyi* invasion influenced total catches. It is assumed that this represents a period when fishing effort was relatively stable, thus satisfying the criterion for the use of method 4. The calculated *MCY* applies only to *T. declivis* and *T. novaezelandiae*.

Using $M = 0.18$ and therefore $c = 0.8$,

$$\begin{aligned} MCY &= 0.8 \times 3\,013 \text{ t} \\ &= 2\,410 \text{ t (rounded to 2400 t)} \end{aligned}$$

(iii) Rest of the EEZ (QMAs 3–6)

Trawl surveys in QMAs 3–6 are not considered to be a suitable means to estimate biomass of jack mackerels, due primarily to the slow towing speed. Landings from JMA 3 have fluctuated widely since 1983–84, and were relatively high in the 1990s due probably to an increased abundance of *T. murphyi*.

For JMA 3 there are no available estimates of biomass and no series of catch data from a period of relatively constant fishing mortality. Therefore, it is not possible to estimate *MCY* for this Fishstock.

The level of risk to the stock by harvesting the population at the estimated *MCY* value cannot be determined.

Estimates of current biomass are not available for any jack mackerel stock, so *CAY* cannot be estimated.

Yield estimates for *T. declivis* and *T. novaezelandiae* are shown in Table 15.

Table 15: Yield estimates for *T. declivis* and *T. novaezelandiae* (t).

Parameter	Fishstock	Estimate
MCY	JMA 1	2 400
	JMA 3	Cannot be determined
	JMA 7	21 600
CAY	All	Cannot be determined

5.5 Other yield estimates and stock assessment results

For *T. declivis* and *T. novaezelandiae* catch-at-age proportions are available for the years 2006–07 through to 2008–09 in JMA 7. These were used to estimate instantaneous total mortality Z values by the Chapman-Robson maximum likelihood method (Chapman & Robson 1960). As a sensitivity analysis the assumed age of recruitment was varied between three and six years (Smith 2011).

For *T. declivis* estimates of Z varied between 0.17 y^{-1} and 0.23 y^{-1} . For *T. novaezelandiae*, Z varied between 0.23 y^{-1} and 0.43 y^{-1} . Estimates were lowest in the 2008–09 year for both species. The accepted value of natural mortality for both species is 0.18 y^{-1} , indicating that estimates of average instantaneous fishing mortality (F) were well below M for *T. declivis* and about equal to M for *T. novaezelandiae*.

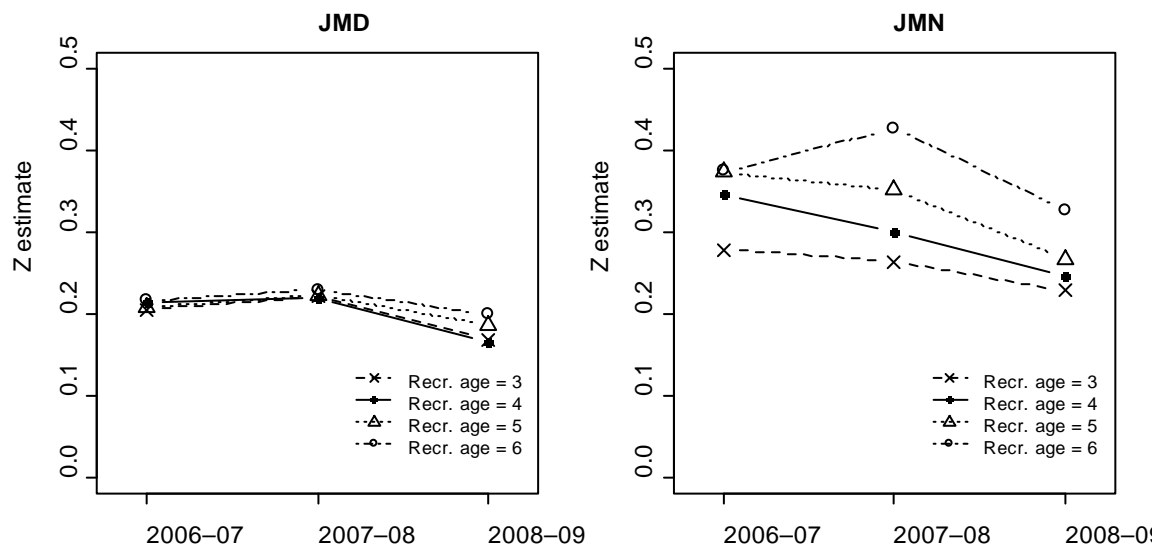

Figure 4: Estimates of instantaneous total mortality (Z) by year for *T. declivis* and *T. novaezelandiae* in JMA 7.

5.6 Other factors

The estimates of MCY given above are likely to be conservative as they do not take into account the presence of the third species, *T. murphyi*, which has been known at times to comprise a substantial proportion of the purse seine catches in the area between Cook Strait and Kaikoura, in the Bay of Plenty and on the east Northland coast, although the proportion of this component has declined considerably since the late 1990s. *T. murphyi* has also been an important component of the west coast North Island jack mackerel trawl fishery but has declined in recent years. Thus, there has been a contraction in the range of this species in New Zealand waters, although it is unknown yet whether this represents a decrease in its overall abundance here. The effect of *T. murphyi* on the range and abundance of the other two species is unknown.

Aerial sightings data were used to produce a time series of relative abundance indices for jack mackerel. The time series covered the period from the beginning of the purse seine fishery in 1976 to 1993. It indicated an increase in abundance in JMA 1 from the early 1990s, and, although the result is not as clear, a similar trend in JMA 3 and JMA 7. These increases were attributed to the invasion of *T. murphyi*.

The validity of this early aerial sightings abundance index is uncertain. Further analysis of these data have been the focus of considerable effort in recent years and the Northern Inshore Working Group had not yet accepted revised abundance indices due to data and model concerns.

JACK MACKERALS (JMA)

The stipulation that catches in JMA 1 and JMA 3 above the original TACs (5970 t and 2700 t, respectively) be accounted for by increases in *T. murphyi* only, is a method of managing this species independently of the other two. This approach was introduced as a means of maintaining stocks of the endemic species while allowing exploitation of increased stocks of *T. murphyi* resulting from its invasion.

The increase in *T. novaezelandiae* catch has predominantly occurred within the Bay of Plenty fishery area. There has been a small decrease in the length of fish caught from the fishery since 2006/07–2008/09, although it is unknown whether the decline in fish size is attributable to an increase in fishing mortality rates, changes in fishing operation or variation in annual recruitment. Age composition data are available for the *T. novaezelandiae* catch from 2006/07–2008/09, but age based sampling was discontinued due to the relatively high inter-annual variability in the age compositions, with the fishery targeting size classes based on market demand.

6. STATUS OF THE STOCKS

Assessment of the status of JMA is complicated by the reporting and management of three species under a single code. This is further complicated by the uncertain ‘status’ of *T. murphyi*. The effect of the *T. murphyi* invasion on stocks of the New Zealand jack mackerels is unknown.

Stock Structure Assumptions

The three species have different levels of mobility and different spatial distributions within New Zealand. *T. murphyi* has been extremely mobile, with a widespread distribution throughout New Zealand during the 1990s, but is now rarely seen in areas where once it was common. The degree to which its biomass has actually declined is difficult to determine and there are no recent reliable estimates of its current spatial distribution. There are reports from hoki surveys in Cook Strait of aggregations of *T. murphyi* lying in deeper water.

T. declivis is also believed to be highly mobile within New Zealand. Because of this, a single biological stock is assumed, but this has not yet been reliably determined. The mobility of *T. novaezelandiae* is assumed to be lower, given that it is a smaller animal with a more northerly and inshore distribution than *T. declivis*. Consequently, there is a higher probability of multiple independent breeding populations for *T. novaezelandiae*.

Fishery Interactions
JMA 1 catches are primarily taken by targeted purse seine. Because jack mackerel often occur in mixed schools with kahawai, particularly towards the end of the fishing year, this can inhibit jack mackerel targeting in this fishery at this time. Interactions with other species are currently being characterised.

Fishery Interactions
JMA 7 catches are primarily taken by targeted midwater trawl. A number of bycatch issues exist with blue mackerel, an important component of this fishery, and the non-availability of ACE for kingfish, blue mackerel, and snapper potentially influences targeting in some sub-areas. Interactions with other species are currently being characterised.

Yield estimates, TACCs and reported landings for the 2016–17 fishing year are summarised in Table 16.

Table 16: Summary of TACCs (t) and reported landings (t) for all three species in the most recent fishing year.

Fishstock		FMA	2016–17 Actual TAC	2016–17 Reported landings
JMA 1	Auckland (East)/ Central (East)	1, 2	10 000	8 890
JMA 3	South-East/Southland/Sub-Antarctic	3, 4, 5, 6	8 780	4 665
JMA 7	Challenger/Central (West)/Auckland (West)	7, 8, 9	32 537	33 802
JMA 10	Kermadec	10	10	0
Total			51 327	47 357

JOHN DORY (JDO)*(Zeus faber)*

Kuparu

**1. FISHERY SUMMARY**

John dory was introduced into the QMS on 1 October 1986 with allowances, TACCs, and TACs in Table 1, except that the TACC for JDO 7 was increased from 131 to 150 t in October 2012, and to 190 t on 1 October 2016.

Table 1: TACs, TACCs and allowances for John dory

Fishstock	Recreational Allowance	Customary non-commercial allowance	Other mortality	TACC	TAC
JDO 1	-	-	-	-	704
JDO 2	-	-	-	-	269.5
JDO 3	-	-	-	-	31.9
JDO 7	4	2	10	190	206
JDO 10	-	-	-	-	10

1.1 Commercial fisheries

John dory are taken mainly as a bycatch of the trawl and Danish seine fisheries. In recent years, around 50–65% of the total reported catch has been taken in JDO 1, and around 20% taken in JDO 2. Recent reported landings by Fishstock are shown in Table 3, while the historical landings and TACC values for the three main JDO stocks are depicted in Figure 1.

The increase in JDO 1 landings after 1986–87 is largely attributed to increased targeting of John dory by trawl and Danish seine. Annual catches reached a peak during 1994/95–1996/97, at about the level of the TACC of 704 t. There was a general decline in annual catches over the subsequent years. In recent years (2011/12–2016/17), catches were maintained at about 350 t per annum. Most of the decline in John dory catch occurred in the Hauraki Gulf-East Northland fishery. Annual catches from the west coast (FMA 9) have been maintained at about 80–140 t over the last 25 years (from 1990/91), predominantly as a bycatch of the snapper, red gurnard and trevally trawl fisheries. Annual catches from the Bay of Plenty fishery (trawl and Danish seine) were about 80–120 t during the same period.

JOHN DORY (JDO)

Annual landings in JDO 2 have never exceeded the TACC and in the mid-90s, were around 50% of the TACC in each year (Figure 1). From 1999–00 to 2002–03 landings were above 200 t, but in recent years landings have decreased, being below about 150 t since 2005–06. Landings from JDO 2 are considered to be approximately equally split between FMAs 2 and 8. Substantial proportions of John dory landings are taken as bycatch in target trawl fisheries for jack mackerels in FMA 8, and as tarakihi and red gurnard bycatch in FMA 2. Landings from JDO 7 increased markedly after 1999–2000, as a result of increasing abundance. JDO 7 is taken largely as a bycatch of FMA 7 trawl fisheries. The JDO 7 TACC has been increased four times since 2003–04 and is currently 190 t (Table 3).

Table 2: Reported landings (t) for the main QMAs from 1931 to 1982.

Year	JDO 1	JDO 2	JDO 3	JDO 7	Year	JDO 1	JDO 2	JDO 3	JDO 7

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns: Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings. Data were aggregated to FMA using methods and assumptions described by Francis & Paul (2013).

Table 3: Reported landings (t) of John dory by Fishstock from 1983–84 to 2016–17 and actual TACCs (t) for 1986–87 to 2016–17. QMS data from 1986–present.

* FSU data.

Overall the majority of John dory catch is reported in the snapper bottom trawl fishery (16%), followed by the John dory bottom trawl (14%) and the tarakihi bottom trawl fisheries (14%). Danish seine accounts for the second largest John dory catch across fishing methods (Figure 2).

Catches of John dory in JDO 1 are predominantly taken through bottom trawl in the snapper (23%), John dory (19%) and trevally (10%) target fisheries. Danish seine, bottom pair trawl and bottom longline comprise the remaining John dory catch by fishing method (Figure 3). John dory catch in JDO 2 are taken predominantly by bottom trawl targeting tarakihi (30%) and gurnard (25%), with mid-water and setnet fishing methods comprising the remainder of catch (Figure 4). John dory in JDO 7 is predominantly caught by bottom trawl targeting flatfish (25%), barracouta (23%) and tarakihi (18%) (Figure 5). Throughout the North Island, the trawl and Danish seine fisheries targeting

JOHN DORY (JDO)

John dory take the majority of their catch targeting snapper (33%) followed by the John dory target fishery (23%) (Figure 6). No data were available for JDO setnet fisheries in the South Island.

Figure 1: Reported commercial landings and TACC for the three main JDO stocks. JDO 1 (Auckland East), JDO 2 (Central East), and JDO 7 (Challenger).

Figure 5: A summary of the proportion of landings of JDO 7 taken by each target fishery and fishing method. The area of each circle is proportional to the percentage of landings taken using each combination of fishing method and target species. The number in the bubble is the percentage. BT = bottom trawl, MW = mid-water (Bentley et al 2012).

Figure 6: A summary of species composition of the reported trawl and Danish seine catch in trips targeting John dory off the North Island. Catch is expressed as the percentage by weight of each species calculated for all trawl and Danish seine trips (Bentley et al 2012).

1.2 Recreational fisheries

John dory is an important recreational species in the north of New Zealand. They are caught using line fishing methods, predominantly on rod and reel with some longline catch.

1.2.1 Management controls

The main method used to manage recreational harvests of John dory is daily bag limits. Fishers can take up to 20 John dory as part of their combined daily bag limit in the Auckland and Kermadec, Central, and Challenger Fishery Management Areas.

1.2.2 Estimates of recreational harvest

There are two broad approaches to estimating recreational fisheries harvest: the use of onsite or access point methods where fishers are surveyed or counted at the point of fishing or access to their fishing activity; and, offsite methods where some form of post-event interview and/or diary are used to collect data from fishers.

The first estimates of recreational harvest for John dory were calculated using an offsite approach, the offsite regional telephone and diary survey approach. Estimates for 1996 came from a national telephone and diary survey (Bradford 1998). Another national telephone and diary survey was carried out in 2000 (Boyd & Reilly 2002). The harvest estimates provided by these telephone diary surveys (Table 4) are no longer considered reliable.

In response to the cost and scale challenges associated with onsite methods, in particular the difficulties in sampling other than trailer boat fisheries, offsite approaches to estimating recreational fisheries harvest have been revisited. This led to the development and implementation of a national panel survey for the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and catch information collected in standardised phone interviews. Recreational catch estimates from the national panel survey are given in Table 4 (from Wynne-Jones et al 2014 and Hartill & Davey 2015).

Table 4: Recreational harvest estimates for John dory stocks. The telephone/diary surveys ran from December to November but are denoted by the January calendar year. The national panel survey ran through the October to September fishing year but is denoted by the January calendar year. Mean fish weights were obtained from boat ramp surveys (for the telephone/diary and panel survey harvest estimates).

Stock	Year	Method	Number of fish	Total weight (t)	CV
JDO 1	1996	Telephone/diary	49 000	87	0.09
	2000	Telephone/diary	129 000	227	0.23
	2012	Panel survey	28 863	36	0.13
JDO 2	2000	Telephone/diary	9 000	16	0.43
	2012	Panel survey	2 000	3	0.33
JDO 3	2012	Panel survey	88	< 1	1.00
JDO 7	2012	Panel survey	1 351	2	0.52
JDO total	2012	Panel survey	32 303	40	0.12

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

No quantitative information is available on the current level of Maori customary non-commercial catch.

1.4 Illegal catch

No quantitative information is available.

1.5 Other sources of mortality

No quantitative information is available.

2. BIOLOGY

John dory are widespread, being found in the eastern Atlantic Ocean, the Mediterranean Sea and around New Zealand, Australia and Japan. They are common in the inshore coastal waters of northern New Zealand, and to a lesser extent in Tasman Bay, to depths of 50 m. In the Hauraki Gulf, adults move to deeper waters during summer, and occasional feeding aggregations occur during winter.

John dory are serial spawners (spawning more than once in a season). There appears to be substantial variation in the time of spawning in New Zealand, with spawning occurring between December and April on the northeast coast. The eggs are large and pelagic, taking 12–14 days to hatch. Initially John dory grow rapidly with both males and females reaching 12 to 18 cm standard length (SL) after the first year. From the second year onwards females grow faster than males and reach a greater maximum length. Females mature at a size of 29 to 35 cm SL and in general, larger females mature earlier in the season and are more fecund. Males mature at 23 to 29 cm SL.

M was estimated using the equation $M = \log_e 100/\text{maximum age}$, where maximum age is the age to which 1% of the population survives in an unexploited stock. Using a maximum observed age of 12 years, M was estimated to equal 0.38. Biological parameters relevant to the stock assessment are shown in Table 5.

JOHN DORY (JDO)

3. STOCKS AND AREAS

In 2012 the stock structure of John dory was reviewed (Dunn & Jones 2013). The approach evaluated patterns in the distribution of catch and CPUE, research survey biomass trends, location of spawning and nursery grounds, size and age compositions, and anecdotal information from the fishery.

John dory have been caught around most of the North Island and the northern South Island, indicating that the QMA boundaries are not biologically appropriate. The analysis suggested five stocks around New Zealand: (1) Hauraki Gulf and east Northland; (2) Bay of Plenty; (3) west coast North Island; (4) southeast North Island; and (5) northern South Island.

Spawning fish and nursery grounds are found in all five stocks. In addition, on the east coast North Island, CPUE analyses support the separation of the Hauraki Gulf, Bay of Plenty, and Hawkes Bay fisheries, and research trawl survey biomass estimates had different trends in Hauraki Gulf and the Bay of Plenty. Very few John dory are found south of Hawkes Bay on the southeast North Island, providing a gap between the east and west coast components of JDO 2. There is relatively strong evidence to separate the northeast and northwest coasts of JDO 1, including fishery CPUE analyses, length and age compositions, and research trawl survey biomass trends. The distribution of John dory on the west coast North Island is continuous between JDO 1 and the northern part of the west coast JDO 2, and the combination of these areas is also supported by CPUE analyses. There is evidence to separate the northern South Island from stocks to the north including the occurrence of unusually large fish on the northern South Island, and CPUE analyses. John dory appear to reach the southern limit of their range off the north and northwest coasts of the South Island.

4. STOCK ASSESSMENT

The yield estimates are based on commercial landings data only and have not changed since the 1992 Plenary Report.

4.1 Estimates of fishery parameters and abundance

An investigation into the stock structure of New Zealand John dory (Dunn & Jones 2013) supported five biological stocks: (1) Hauraki Gulf and east Northland, (2) Bay of Plenty, (3) West coast North Island, (4) Southeast North Island, and (5) Northern South Island. The first three stocks are found within JDO 1, the fourth consists of the east coast portion of JDO 2 and the fifth of JDO 7 and the portion of JDO 2 located on the south and east coast of the North Island.

JDO 1

Relative abundance indices have been obtained from trawl surveys of the Bay of Plenty, west coast North Island, and Hauraki Gulf within the JDO 1 Fishstock (Table 6). However, there was a change in the configuration of the trawl gear following the 1988 trawl survey. Modifications to the trawl gear may have resulted in a change in the catchability of John dory part way through the time series.

Therefore, surveys conducted between 1982 and 1988 and from 1989 onwards should be considered separately for comparisons of biomass indices to be valid.

In 2018, the CPUE indices for the three sub-areas within JDO 1 (Hauraki Gulf and east Northland, Bay of Plenty, and west coast North Island) were updated to 2016–17. The catch and effort data set included individual bottom trawl records from trawl targeting a range of inshore finfish species (BAR, TAR, TRE, GUR, SNA and JDO). The landed catch of John dory from a trip was allocated to the individual trawl records in proportion to the estimated catch. The analyses used a delta-lognormal CPUE model incorporating positive catch (lognormal) and presence/absence (binomial) components. For a number of analyses, different trends were apparent between the lognormal and binomial CPUE models. Further investigation indicated that the differences may have been attributable to changes in the recording of smaller John dory catches over the time period. Potential biases introduced by changes in catch reporting are likely to be adequately accounted for by applying the delta-lognormal approach.

Hauraki Gulf and east Northland (part of JDO 1)

In Hauraki Gulf and east Northland, the standardised CPUE indices fluctuated during the 1990s and 2000s and then steadily declined from 2004–05 to 2012–13 and then increased relatively slowly during 2013–14 to 2016–17 (Figure 7).

Figure 7: CPUE indices of abundance for Hauraki Gulf and east Northland (part of JDO 1) (combined model of catch rates in mixed species bottom trawl tows). Vertical lines show the 95% confidence intervals.

Bay of Plenty (part of JDO 1)

The standardised CPUE series declined during the late 1990s, remained relatively stable during the 2000s, dropped in 2012–13 to 2013–14 and then increased from 2015–16 to 2016–17 to just below the series mean (Figure 8).

Figure 8: CPUE indices of abundance for the Bay of Plenty (part of JDO 1) (combined model of catch rates in mixed species bottom trawl tows). Vertical lines show the 95% confidence intervals.

West Coast North Island (western JDO 1 and western JDO 2)

The standardised CPUE series suggests that biomass has fluctuated over the study period. CPUE indices were at a high level in 2010–11 to 2012–13 and declined over the subsequent four years (to 2016–17) to below the series mean (Figure 9).

Figure 9: CPUE indices of abundance for the West Coast North Island (western JDO 1 and western JDO 2) (combined model of catch rates in mixed species bottom trawl tows). Vertical lines show 95% confidence intervals.

Establishing B_{MSY} compatible reference points for JDO 1

In 2012, the Working Group accepted mean standardized bottom trawl CPUE for the period 1994–95 to 2010–11 as B_{MSY} -compatible proxies for each of the three JDO 1 sub-stocks. All three series were based on combined positive catch and probability of capture models derived from event scale fishing events (i.e. Tow). JDO abundance tends to fluctuate in cycles, according to recruitment, and the period chosen included two periods of high abundance and high catch. The Working Group accepted the default Harvest Strategy Standard definitions that the Soft and Hard Limits would be one half and one quarter the target for each sub-stock, respectively.

Southeast North Island (part of JDO 2)

The standardised CPUE series suggests an increase in abundance from a low in the mid-1990s to a peak in 2000–01, followed by a steady decline to a series low in 2010–11 (Figure 10).

Figure 10: CPUE indices of abundance for the Southeast North Island (part of JDO 2), combined model of catch rates in mixed species bottom trawl tows (Dunn & Jones 2013). Vertical lines show the 95% credible intervals. Years labeled as year-ending (i.e., 1990 is 1989–90).

Northern South Island (JDO 7, and part of JDO 2)

In 2014, the CPUE indices for the Northern South Island zone (JDO 7, and part of JDO 2) were revised and updated to include data to 2012–13 (Langley 2014). The CPUE index was based on JDO bycatch from the following bottom trawl targets: BAR, FLA, GUR, JDO, JMA, RCO and TAR, in Statistical Areas: 033–039.

The Southern Inshore Working Group agreed that the west coast South Island trawl survey series appears to monitor trends in abundance of John dory, particularly recruited biomass (defined as fish of at least 25 cm TL) (Figure 11). Length frequency trends for the John dory survey catch from the west coast South Island and Tasman Bay/Golden Bay are presented in Figure 12. Smaller (20–35 cm) fish tend to be caught in the latter survey region. The 2017 1+ cohort (21–32 cm) is the strongest in the time series. Biomass levels were low before 2003, with recruited biomass increasing two to three fold since then. The 2017 biomass estimate is the second highest in the time series, down slightly from 2015.

The last four trawl surveys (2011, 2013, 2015 and 2017) have estimated the recruited biomass of John dory in the WCSI area to be at the highest level of the entire time series (Figure 11). For the survey area as a whole, the 2017 estimate is the second highest in the time series, down slightly from the time series high in 2015. The 1+ cohort, visible in length frequencies, is stronger than any previous survey in the time series, suggesting that the biomass will remain high, at least in the short term.

JOHN DORY (JDO)

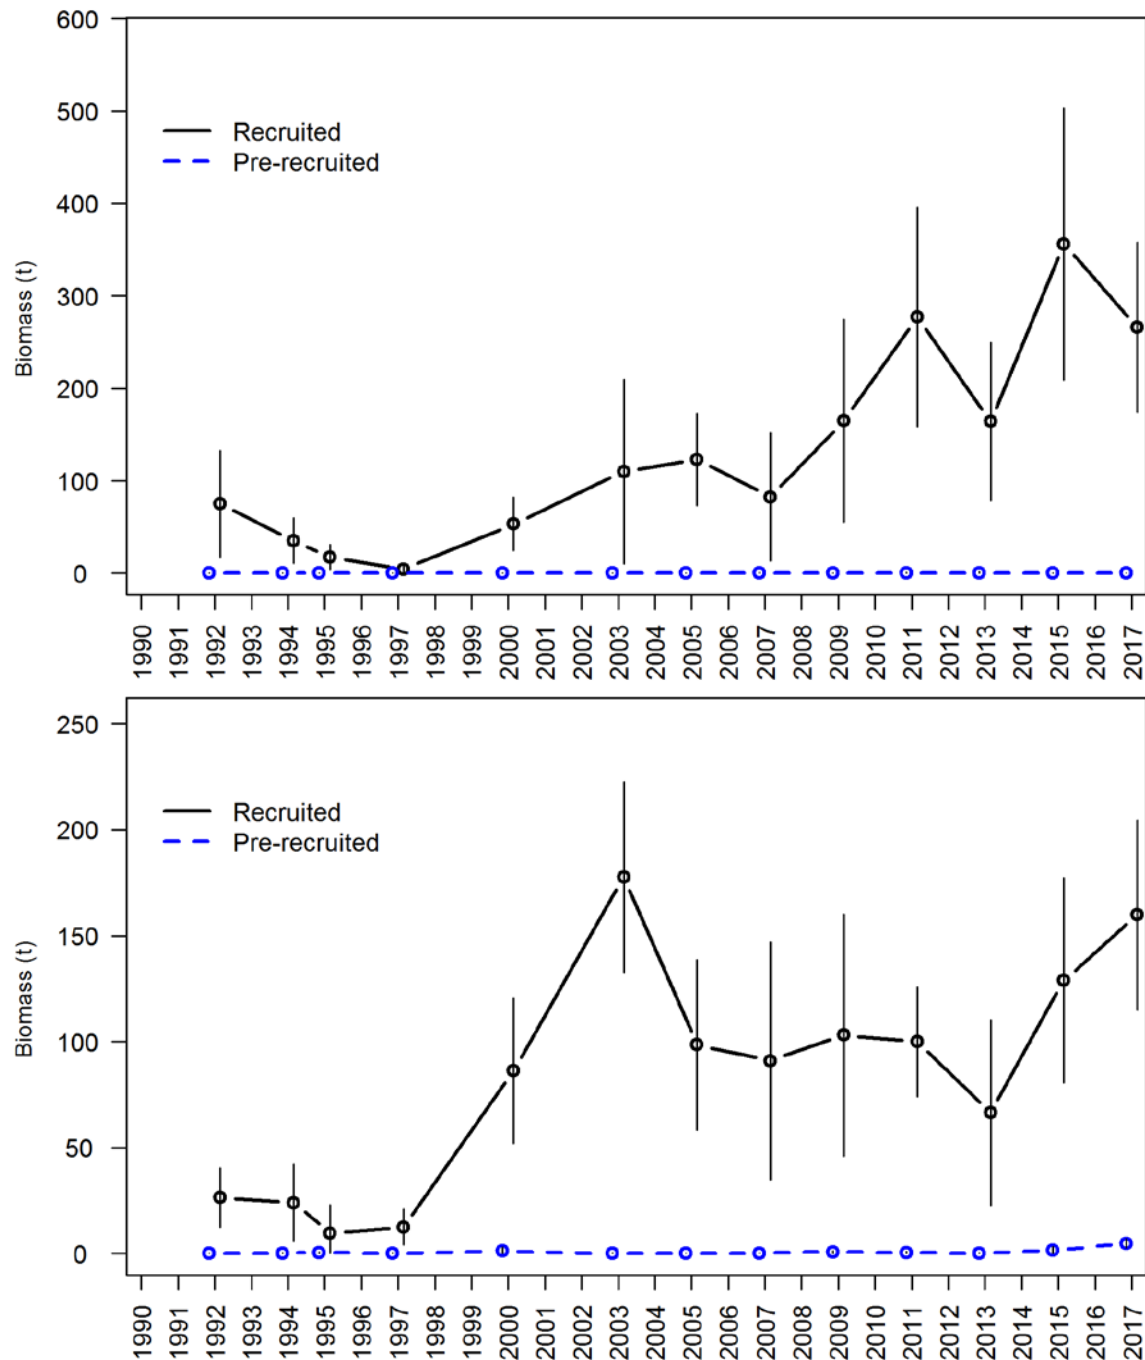

Figure 11: WCSI trawl survey Biomass estimates of recruited and pre-recruit John dory for the west coast South Island strata (top plot) and Tasman Bay/Golden Bay (bottom plot). Error bars are \pm two standard deviations. John dory are assumed to recruit to the commercial fishery at 25 cm TL.

The standardised CPUE series shows a similar trend to the trawl survey biomass index, with a large increase in biomass between the late 1990s and early 2000s, which has persisted to the present (2013) (Figure 13).

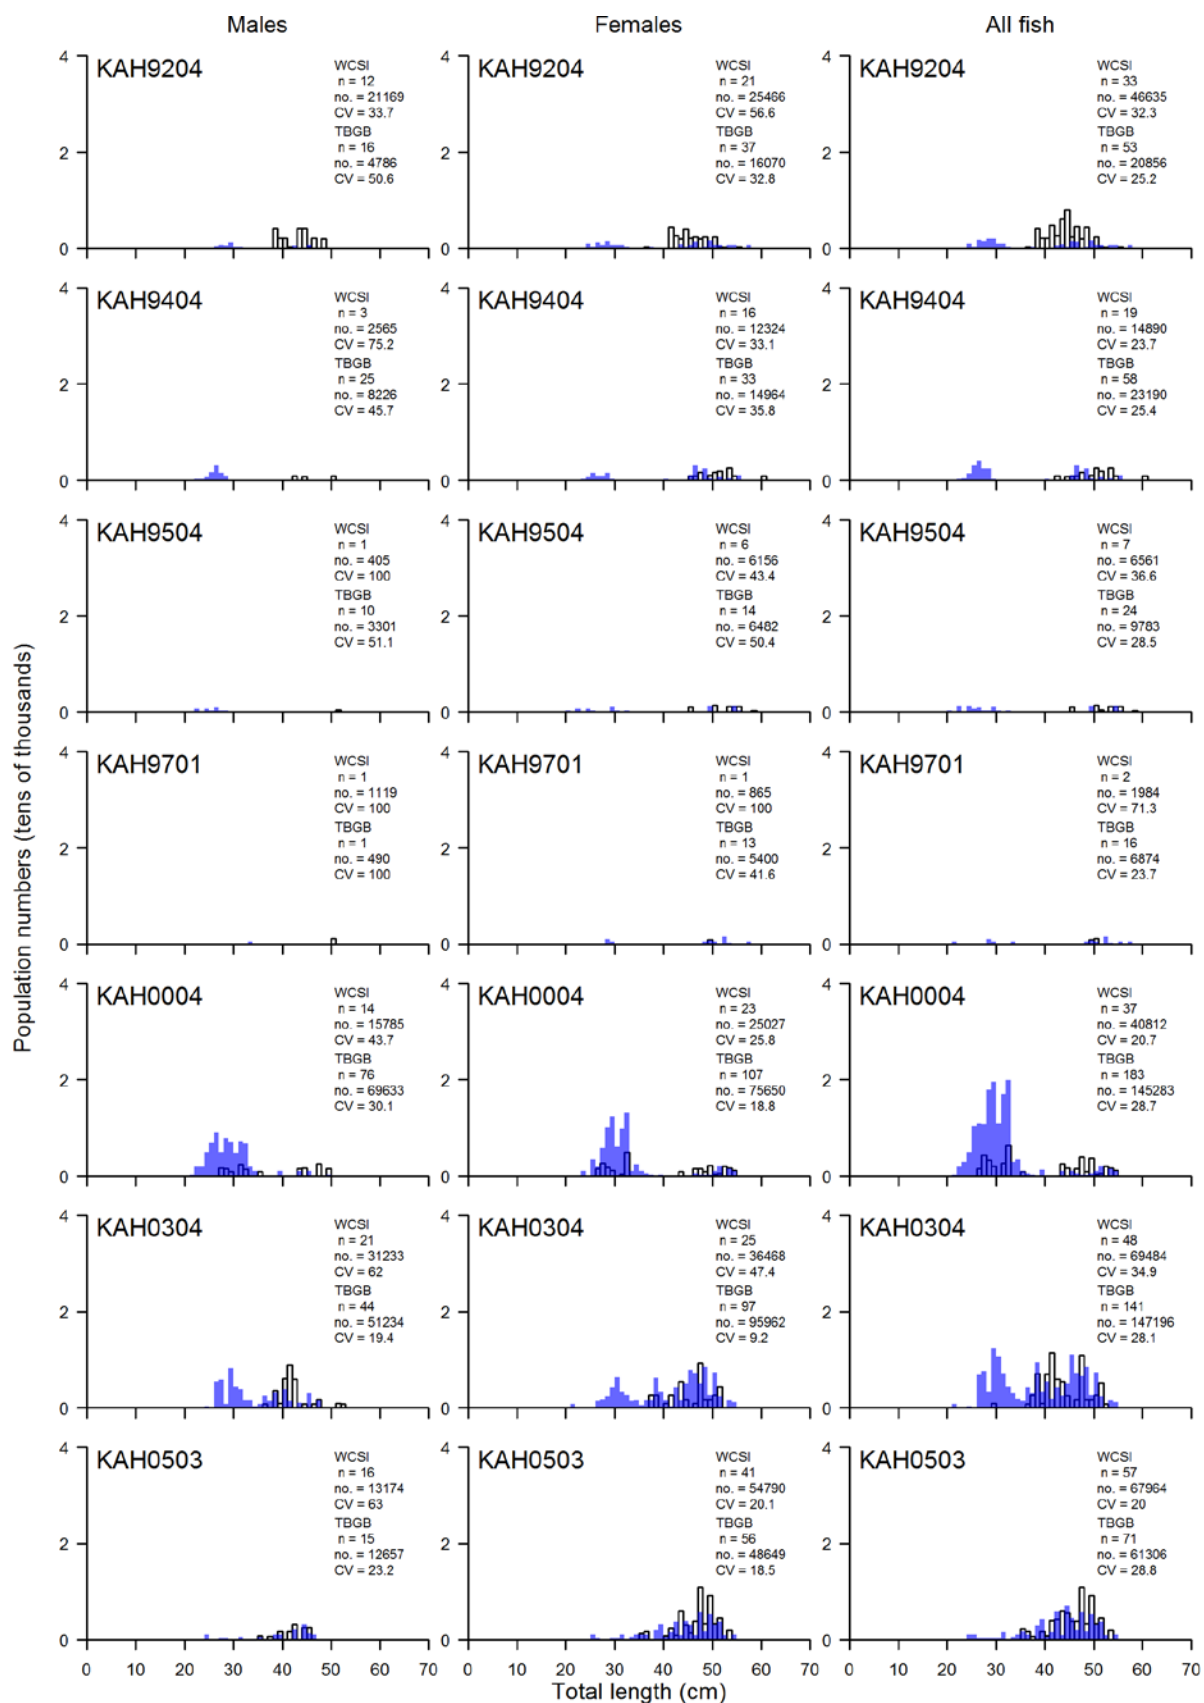

Figure 12: Scaled population length frequency distributions for John dory in 30–400 m for west coast (white bars) and Tasman Bay/Golden Bay (blue bars), from WCSI surveys. n = number of fish measured, no. = scaled population number, CV = coefficient of variation (%). [Continued on next page].

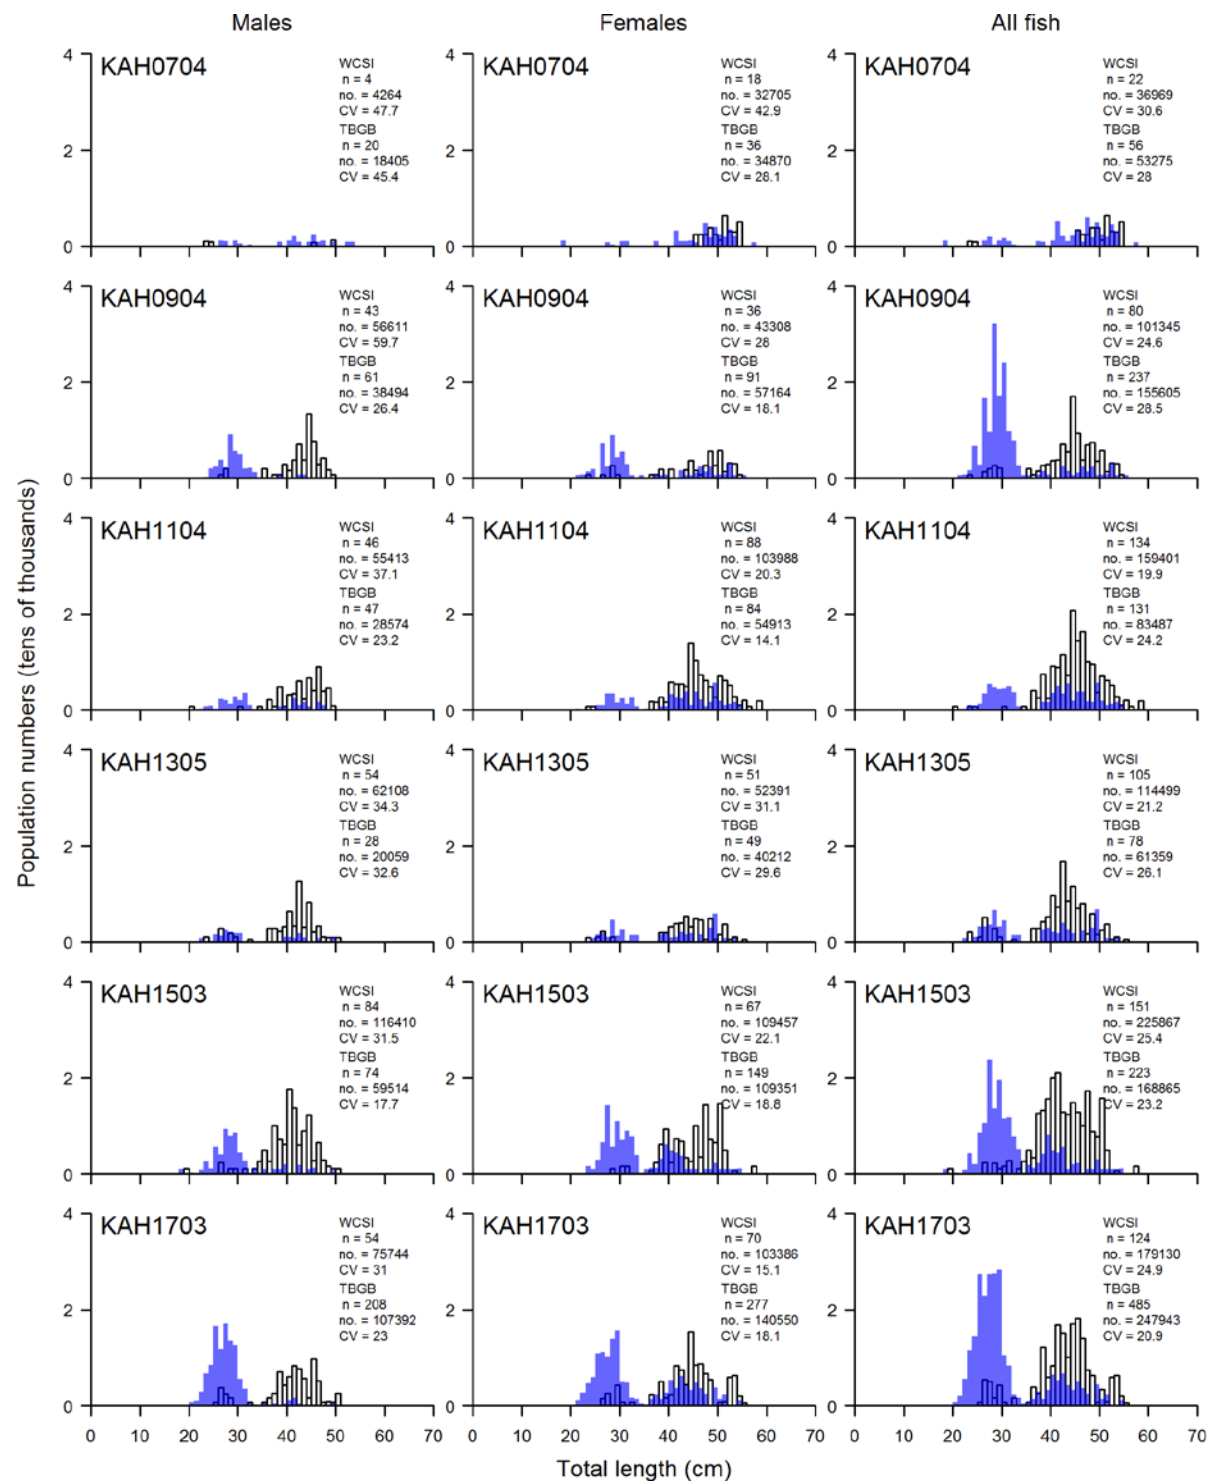

Figure 12 [Continued].

4.3 Yield estimates and projections

The level of risk to the stock by harvesting the population at the estimated MCY value cannot be determined.

No estimates of current biomass are available which would permit the estimation of *CAY*.

4.4 Other yield estimates and stock assessment results

Current estimates of yield are based upon commercial landings only and are assumed to be independent of the non-commercial catch. There was no indication that John dory were overfished at the time of the introduction of the QMS.

5.0 STATUS OF THE STOCKS

• JDO 1 (Hauraki Gulf and east Northland)

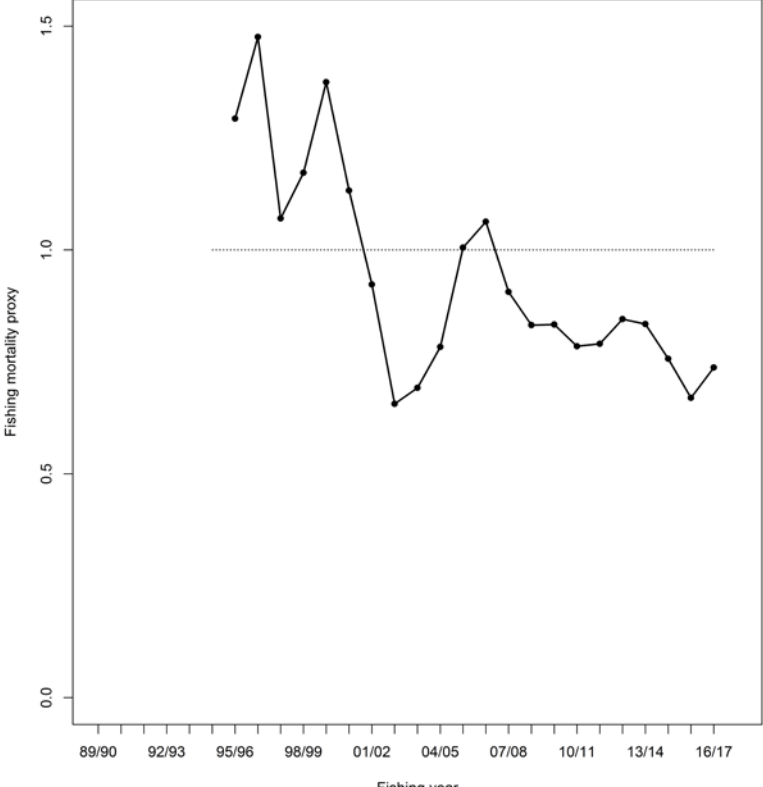

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Standardised CPUE
Reference Points	Interim Target: Mean of the CPUE indices for John dory in Hauraki Gulf and east Northland from combined binomial and lognormal models from 1995–96 to 2010–11 Soft Limit: 50% of target Hard Limit: 25% of target Overfishing threshold: F_{MSY}
Status in relation to Target	Very Unlikely (< 10%) to be at or above the target
Status in relation to Limits	Soft Limit: Unlikely (< 40%) to be below Hard Limit: Very Unlikely (< 10%) to be below
Status in relation to Overfishing	Unlikely (< 40%) that overfishing is occurring

Historical Stock Status Trajectory and Current Status

Standardised CPUE indices for John dory in Hauraki Gulf and east Northland from combined binomial and lognormal models of catch rate in bottom trawl tows in a mixed target fishery. Broken horizontal lines indicate the target and soft limit. The commercial catch from the area is also presented. Vertical lines show the 95% confidence intervals.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	The CPUE indices steadily declined from the mid-2000s to approximate the soft limit in 2012–13. The CPUE indices have increased over the last four years and the 2016–17 index is 65% of the target CPUE level.

Recent Trend in Fishing Intensity or Proxy	 <p>Relative fishing mortality proxy derived from total area catch divided by CPUE indices from the recent CPUE analysis (black points). The horizontal line represents the average fishing mortality in the period used to define the reference points.</p> <p>The fishing mortality proxy indicates that fishing mortality has been lower in the recent period as total catch from the fishery has declined more than the decline in CPUE and catches have remained low during the last four years, while CPUE increased. The absolute level of fishing mortality that corresponds to the target biomass level is unknown.</p>
Other Abundance Indices	The trend in Danish seine CPUE indices from the Hauraki Gulf fishery is comparable to the BT CPUE index (to 2013–14).
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Annual catches and fishing mortality have been relatively low over the last five years. There has been a modest increase in the CPUE indices over the last 4 years indicating the stock is rebuilding slowly. It is likely that recruitment had been low during the preceding period. The continued rebuilding of the stock to the target biomass level will depend on future levels of recruitment.
Probability of Current Catch or TAC causing Biomass to remain below or to decline below Limits	Soft Limit: Unlikely (< 40%) at the current catch levels (which are the lowest of the time-series) Hard Limit: Very Unlikely (< 10%) over the next five years at current catch levels
Probability of Current Catch or TAC causing Overfishing to continue or to commence	Current catch is Unlikely (< 40%) to cause overfishing

Assessment Methodology and Evaluation		
Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Standardised CPUE	
Assessment Dates	Latest assessment: 2018	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Catch and effort data	1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- Lack of information on incoming recruitment	

Qualifying Comments
As CPUE is at a relatively low level the stock status should be routinely monitored. It is intended to update the CPUE analysis in 2021.

Fishery Interactions
John dory is taken on the east coast by bottom trawl and Danish seine targeted at John dory and snapper. Interactions with other species are currently being characterised.

- **JDO 1 (Bay of Plenty)**

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Standardised CPUE
Reference Points	Interim Target: Mean of the CPUE indices for John dory in Bay of Plenty from combined binomial and lognormal models from 1994–95 to 2010–11 Soft Limit: 50% of target Hard Limit: 25% of target Overfishing threshold F_{MSY}
Status in relation to Target	Unlikely (< 40%) to be at or above the target
Status in relation to Limits	Soft Limit: Very Unlikely (< 10%) to be below Hard Limit: Very Unlikely (< 10%) to be below
Status in relation to Overfishing	Likely (> 60%) that overfishing is occurring

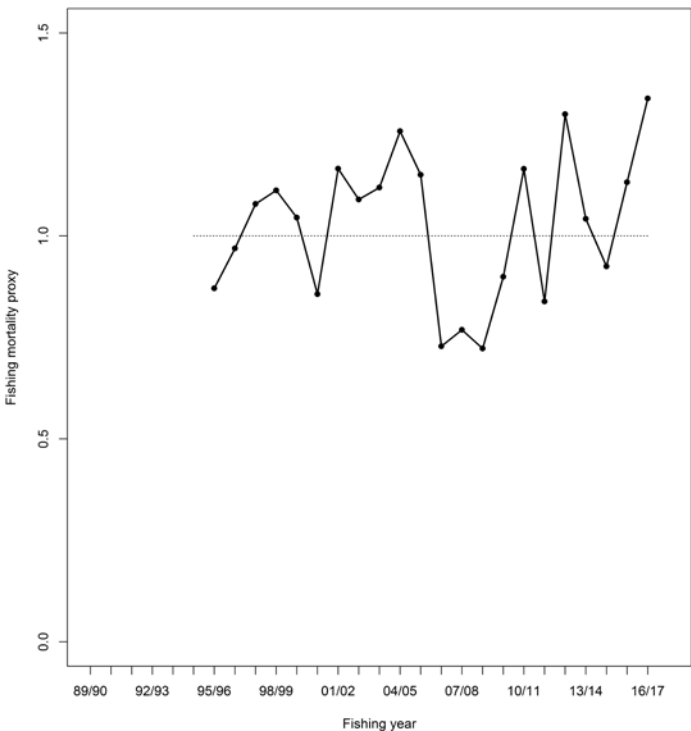

Historical Stock Status Trajectory and Current Status

Standardised CPUE indices for John dory in Bay of Plenty from combined binomial and lognormal models of catch rate in bottom trawl tows in a mixed target fishery. Broken horizontal lines indicate the target and soft limit. The total catch from the area is also presented. Vertical lines show the 95% confidence intervals.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy

The CPUE indices fluctuated over the time-series and reached the lowest level in 2012–13. The CPUE indices increased in subsequent years and the 2016–17 index was at 85% of the target biomass level.

Recent Trend in Fishing Mortality or Proxy	 <p>Relative fishing mortality proxy derived from total area catch divided by CPUE indices from the recent CPUE analysis (black points). The horizontal line represents the average fishing mortality in the period used to define the reference points.</p> <p>The fishing mortality proxy has increased since 2008–09 and in 2016–17 was 34% higher than the reference (F_{MSY} proxy) level.</p>
Other Abundance Indices	The general trend in Danish seine CPUE indices from the Bay of Plenty fishery is comparable to the BT CPUE index (to 2013–14).
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Annual catches have increased considerably over the last three years following the increase in abundance (as indexed by CPUE). There has been an increasing trend in fishing mortality over the last 8 years and fishing mortality in 2016–17 was the highest in the series and considerably higher than the reference level. The current (higher) level of the fishing mortality may cause the stock to begin to decline.
Probability of Current Catch or TAC causing Biomass to remain below or to decline below Limits	Soft Limit: Unlikely (< 40%) at current catch levels Hard Limit: Very Unlikely (< 10%) at current catch levels
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Likely (> 60%) at the current level of catch

Assessment Methodology and Evaluation		
Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Fishery characterisation and standardised CPUE	
Assessment Dates	Latest assessment: 2018	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- 2018 CPUE analysis	1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	-	

JOHN DORY (JDO)

Major Sources of Uncertainty

-

Qualifying Comments

Stock biomass is variable, probably in response to recruitment variation, and the stock abundance had increased in recent years. This makes it difficult to predict future trends without recruitment information. Total fishing effort by the Danish seine fleet increased in 2015–16 to 2016–17, while effective effort in the trawl fishery also increased in the same period.

Fishery Interactions

John dory is taken in the Bay of Plenty by bottom trawl targeted at John dory, snapper, trevally, tarakihi and gurnard; and by Danish seine targeted at snapper and gurnard. Interactions with other species are currently being characterised.

• JDO 1 (West Coast North Island)

Stock Status

Year of Most Recent Assessment 2018

Assessment Runs Presented Standardised CPUE

Reference Points

Interim Target: Mean of the CPUE indices for John dory on West Coast North Island from combined binomial and lognormal models from 1994–95 to 2010–11
Soft Limit: 50% of target
Hard Limit: 25% of target
Overfishing threshold: F_{MSY}

Status in relation to Target Unlikely (< 40%) to be at or above the target

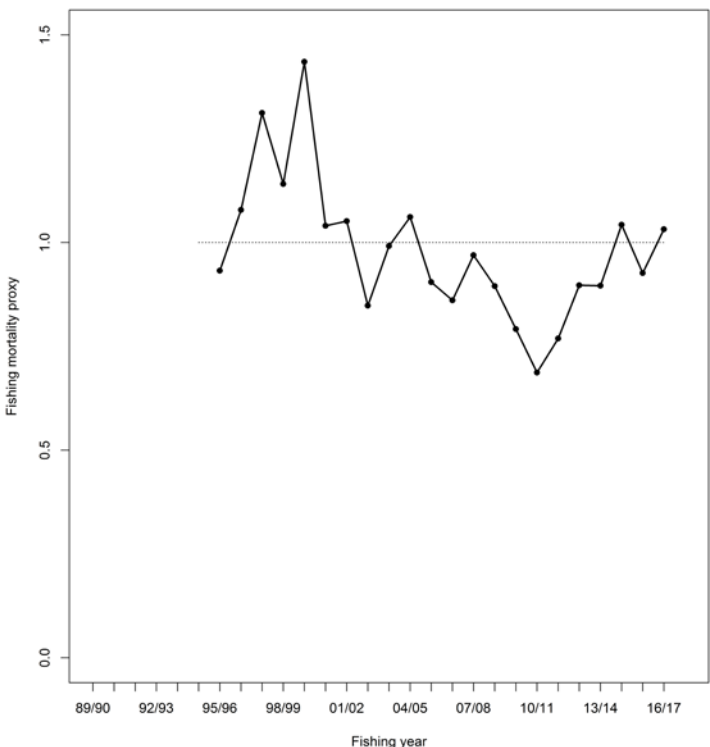

Status in relation to Limits
Soft Limit: Unlikely (< 40%) to be below
Hard Limit: Very Unlikely (< 10%) to be below

Status in relation to Overfishing About as Likely as Not (40–60%) to be occurring

Historical Stock Status Trajectory and Current Status

Standardised CPUE indices for John dory in West Coast North Island from combined binomial and lognormal models of catch rate in bottom trawl tows in a mixed target fishery. Broken horizontal lines indicate the target and soft limit. Vertical lines show the 95% confidence intervals. Commercial catch represents the catch from this area.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	CPUE indices have fluctuated over the time series. CPUE indices were at the highest level in 2010–11 to 2012–13 and declined over the next four years. The 2016–17 CPUE index is at 79% of the target biomass level.
Recent Trend in Fishing Intensity or Proxy	 <p>Relative fishing mortality proxy derived from total area catch divided by CPUE indices from the recent CPUE analysis (black points). The horizontal line represents the average fishing mortality in the period used to define the reference points.</p> <p>Fishing mortality was at a relatively low level in 2010–11 to 2012–13 (corresponding to the high CPUE indices). Fishing mortality has been maintained at about the reference level during 2014–15 to 2016–17.</p>
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Likely to fluctuate above the soft limit.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unlikely (< 40%) at current catch levels Hard Limit: Very Unlikely (< 10%) at current catch levels
Probability of Current Catch or TACC causing Overfishing to continue or to commence	About as Likely as Not (40 – 60% %) at current catch levels

Assessment Methodology and Evaluation	
Assessment Type	Level 2 - Partial Quantitative Stock Assessment
Assessment Method	Fishery characterisation and standardised CPUE

JOHN DORY (JDO)

Changes to Model Structure and Assumptions	-
Major Sources of Uncertainty	- The stock relationship between JDO 1 and JDO 2

Qualifying Comments

-

Fishery Interactions

John dory is taken on the west coast by bottom trawl targeted at snapper trevally, gurnard and tarakihi. Interactions with other species are currently being characterised.

• JDO 2 (Southeast North Island)

Stock Status	
Year of Most Recent Assessment	2013
Assessment Runs Presented	Standardised CPUE
Reference Points	Interim Target: Mean of the CPUE indices for John dory in South East coast of the North Island from combined binomial and lognormal models from 1989–90 to 2010–11 Soft Limit: 50% of target Hard Limit: 25% of target Overfishing threshold F_{MSY}
Status in relation to Target	Unlikely (< 40%) to be at or above the target
Status in relation to Limits	Soft Limit: About as Likely as Not (40–60%) to be below Hard Limit: Unlikely (< 10%) to be below
Status in relation to Overfishing	Unknown

Historical Stock Status Trajectory and Current Status

Standardised CPUE indices for John dory in Southeast North Island from combined binomial and lognormal models of catch rate in bottom trawl trips in a mixed target fishery (Dunn & Jones 2013). Broken horizontal line indicates the mean from 1989–90 to 2010–11; Bars represent catch from this area.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	The CPUE series has fluctuated with a cyclical trend. The data points since 2006–07 have been below the long-term mean. 2010–11 is the lowest in the series.
Recent Trend in Fishing Intensity or Proxy	Unknown
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Without information on recruitment, it is not possible to predict how the stock will respond in the next few years.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Likely (> 60%) Hard Limit: About as Likely as Not (40–60%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unknown

Assessment Methodology and Evaluation		
Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Fishery characterisation and standardised CPUE	
Assessment Dates	Latest assessment: 2013	Next assessment: Unknown
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Catch and effort data	1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- The stock relationship between JDO 1 and JDO 2 - Lack of information on incoming recruitment	

Qualifying Comments
As the John dory fishery in FMAs 1 and 9 has a long history, it is not possible to infer stock status from abundance trends from only the last 22 years. This sub-stock appears to be cyclical, probably in response to recruitment variation. This makes it difficult to predict future trends without recruitment information.

Fishery Interactions
John dory is taken on the east coast by bottom trawl targeted primarily at tarakihi and red gurnard. Interactions with other species are currently being characterised.

- JDO 7 (Northern South Island)**

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Trawl survey biomass index (2017) and standardised CPUE (2014)
Reference Points	Interim Target: Mean total biomass from the West Coast South Island trawl survey (WCSI and TBGB) from 1992 to 2011 Soft Limit: 50% of target Hard Limit: 25% of target Overfishing threshold F_{MSY}
Status in relation to Target	Very Likely (> 90%) to be at or above the target
Status in relation to Limits	Soft Limit: Very Unlikely (< 10%) to be below Hard Limit: Very Unlikely (< 10%) to be below
Status in relation to Overfishing	Overfishing is Very Unlikely (< 10%) to be occurring

Historical Stock Status Trajectory and Current Status

Biomass trends from the west coast South Island inshore trawl survey time series. Error bars are \pm two standard deviations. The solid blue line represents the interim target and dashed blue and red lines the soft and hard limits, respectively.

A comparison of trends in trawl survey biomass estimates (total biomass, WCSI), CPUE indices and the commercial catch relative to the TACC. The dashed line represents the interim target biomass level relative to the trawl survey biomass indices.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy

The trawl survey series declined through the 1990s then increased between 1997–98 and 2003–04. The 2017 estimate is the second highest in the time series, down slightly from the 2015 estimate and continues an overall increasing trend since 1997. The series has been above the long term mean since 2000–01.

	Trends in CPUE are comparable to trawl survey biomass trends.
Recent Trend in Fishing Intensity or Proxy	The commercial catch trends generally followed those of the trawl survey biomass estimates up to 2006–07. Since then, the annual catch has been maintained at about the annual TACC level, while trawl survey biomass has increased.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	Length frequency analysis from the West Coast South Island trawl survey showed very good recruitment in 2000, 2003 and 2009 and these are probably supporting the high biomass at this time. Recruitment from the 2011 and 2013 surveys was more modest but was again high in 2015 and 2017.

Projections and Prognosis

Stock Projections or Prognosis	The stock is currently at a relatively high level, above the interim target biomass level, and previous high catches appear to have been sustained by intermittent high recruitment. The strong 1+ year class seen in 2017 is likely to sustain biomass levels, at least in the short term.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unlikely (< 40%) Hard Limit: Very Unlikely (< 10%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%), for TACC and current catch. Non target species so that even if abundance declines considerably the exploitation rates are unlikely to substantially increase.

Assessment Methodology and Evaluation

Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Evaluation of survey biomass and length frequencies. Standardised CPUE	
Assessment Dates	Latest assessment: 2018 (Survey) 2014 (CPUE)	Next assessment: 2020 (survey)
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- West Coast South Island trawl survey - Survey length frequency - CPUE	1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	- More complete data set obtained for CPUE analysis	
Major Sources of Uncertainty	- The stock relationship between JDO 7 and JDO 2	

Qualifying Comments

-

Fishery Interactions

John dory are primarily taken in conjunction with the following QMS species: barracouta, red cod, stargazer, red gurnard and tarakihi in the Northern South Island bottom trawl fishery. Interactions with other species are currently being characterised.

KAHAWAI (KAH)

(*Arripis trutta* and *Arripis xylabion*)
Kahawai

**1. FISHERY SUMMARY**

Kahawai (*Arripis trutta*) and Kermadec kahawai (*Arripis xylabion*) were introduced into the QMS on 1 October 2004 under a single species code, KAH. Within the QMS, kahawai management is based on six QMAs (KAH 1, KAH 2, KAH 3, KAH 4, KAH 8 and KAH 10).

These QMAs differ from the Management Areas used before kahawai were introduced into the QMS. The definitions of KAH 1, KAH 2 and KAH 10 remain unchanged, but KAH 4 was formerly part of KAH 3, as was that part of KAH 8 which is south of Tirua Point. The area of KAH 8 which is north of Tirua point was formerly called KAH 9.

TACs totalling 7 612 t were set on introduction into the QMS. These TACs were based on a 15% reduction from both the level of commercial catch and assumed recreational use prior to introducing kahawai into the QMS. The Minister reviewed the TACs for kahawai for the 2005–06 fishing year. Subsequently, he decided to reduce TACs, TACCs and allowances by a further 10% as shown in Table 1.

Table 1: KAH allowances, TACCs, and TACs, 1 October 2010.

Fishstock	Recreational Allowance	Customary Non-Commercial Allowance	Other mortality	TACC	TAC
KAH 1	900	200	45	1 075	2 200
KAH 2	610	185	30	705	1 530
KAH 3	390	115	20	410	935
KAH 4	4	1	0	9	14
KAH 8	385	115	20	520	1 040
KAH 10	4	1	0	9	14

1.1 Commercial fisheries

Commercial fishers take kahawai by a variety of methods. Purse seine vessels take most of the catch; however, substantial quantities are also taken seasonally in set net fisheries and as a bycatch in longline and trawl fisheries.

The kahawai purse seine fishery cannot be understood without taking into account the other species that the vessels target. The fleet, which is based in Tauranga, preferentially targets skipjack tuna (*Katsuwonus pelamis*) between December and May, with very little bycatch. When skipjack are not available, usually from June through to November, the fleet fishes for a mix of species including

KAHAWAI (KAH)

kahawai, jack mackerels (*Trachurus* spp.), trevally (*Pseudocaranx dentex*) and blue mackerel (*Scomber australasicus*). These are caught 'on demand' as export orders are received (to reduce product storage costs). However, since the mackerels and kahawai school together there is often a bycatch of kahawai resulting from targeting of mackerels. Historical estimated kahawai landings are shown in Table 2 from 1931 to 1982. Reported landings, predominantly of *A. trutta*, are shown for 1962 up to and including 1982 in Table 3 by calendar year for all areas combined, and from 1983–84 onwards by fishing year and by historic management areas in Table 4 and by QMAs in Table 5. The historical landings and TACC for the main KAH stocks are depicted in Figure 1.

Table 2: Reported landings (t) for the main QMAs from 1931 to 1982.

Notes:

The 1931–1943 years are April–March but from 1944 onwards are calendar years.

Data up to 1985 are from fishing returns; Data from 1986 to 1990 are from Quota Management Reports. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting.

Table 3: Reported total landings (t) of kahawai from 1970 to 1982. Note that these data include estimates of kahawai from data where kahawai were reported within a general category of ‘mixed fish’ rather than separately as kahawai.

Year	Landings	Year	Landings	Year	Landings
1962	76	1969	234	1976	729
1963	81	1970	294	1977	1 461

Source: 1962 to 1969 - Watkinson & Smith (1972); 1970 to 1982 - Sylvester (1989).

Before 1988 there were no restrictions in place for the purse seine fishery.

Table 4: Reported landings (t) of kahawai by management areas as defined prior to 2004 from 1983–84 to 2003–04. Estimates of fish landed as bait or as ‘mixed fish’ are not included. Data for the distribution of catches among management areas and total catch are from the FSU database through to 1987–88 and from the CELR database after that date. Total LFRR or MHR values are the landings reported by Licensed Fish Receivers (to 2000–01) or on Monthly Harvest returns (to 2003–04).

A total commercial catch limit for kahawai was set at 6 500 t for the 1990–91 fishing year, with 4 856 t set aside for those harvesting kahawai by purse seine (Table 6). Before the 2002–03 fishing year a high proportion of the purse seine catch was targeted, but in recent years approximately half of the landed catch has been reported as a bycatch while targeting other species with purse seine gear.

In KAH 1, a voluntary moratorium was placed on targeting kahawai by purse seine in the Bay of Plenty from 1 December 1990 to 31 March 1991, which was extended from 1 December to the Tuesday after Easter in subsequent years. While total landings decreased in 1991–92, landings in KAH 1 increased, and in 1993–94 the competitive catch limit for purse seining in KAH 1 was reduced from 1 666 t to 1 200 t. Purse seine catches reported for KAH 9 were also included in this reduced catch limit, although seining for kahawai on the west coast of the North Island ceased after the reduction in the KAH 1 purse seine limit. Purse seine catch limits were reached in KAH 1 between 1998–99 and 2000–01 and in 2003–04.

Prior to the introduction to the QMS, no change was made to the purse seine limit of 851 t for KAH 2. The KAH 2 purse seine fishery was closed early due to the catch limit being reached before the end of the season in each year between 1991–92 and 1995–96 and between 2000–01 and 2001–02.

KAHAWAI (KAH)

Table 5: Prorated landings (t) of kahawai by the Fishstocks defined in 2004 for the fishing years from 1998–99 and the present. Distribution of data were derived by linking through the trip code, catch landing data (CLD), statistical areas and landing points and prorating to CLD totals. Landings since 2004–05 are from QMS MHR data. The TACC is provided for those years since the introduction to the QMS.

Within KAH 3, the kahawai purse seine fleet has voluntarily agreed since 1991–92 not to fish in a number of near-shore areas around Tasman and Golden Bays, the Marlborough Sounds, Cloudy Bay, and Kaikoura. The main purpose of this agreement is to minimise local depletion of schools of kahawai found in areas where recreational fisheries occur, and to minimise catches of juveniles. The purse seine catch limit for KAH 3 was reduced from 2 339 to 1 500 tonnes from 1995–96. Purse seine catch limits have never been reached in KAH 3.

Table 6: Reported catches (t) by purse seine method and competitive purse seine catch limit (t) from 1990–91 to 2003–04. All data are from weekly reports furnished by permit holders to the Ministry of Fisheries except those for 1993–94 which are from the CELR database. Fishstocks are as defined prior to 2004.

By March 1991 when the catch limit was imposed, the purse seine catch had already exceeded 2339 t and the fishery was immediately closed. As the catch already exceeded 2339 t before the Minister's decision was announced, an extra 500 t was allocated to cover kahawai bycatch only.
§ Combined landings from KAH 9 and KAH 1 were limited to 1200 t., * Purse seine fishery for kahawai closed.

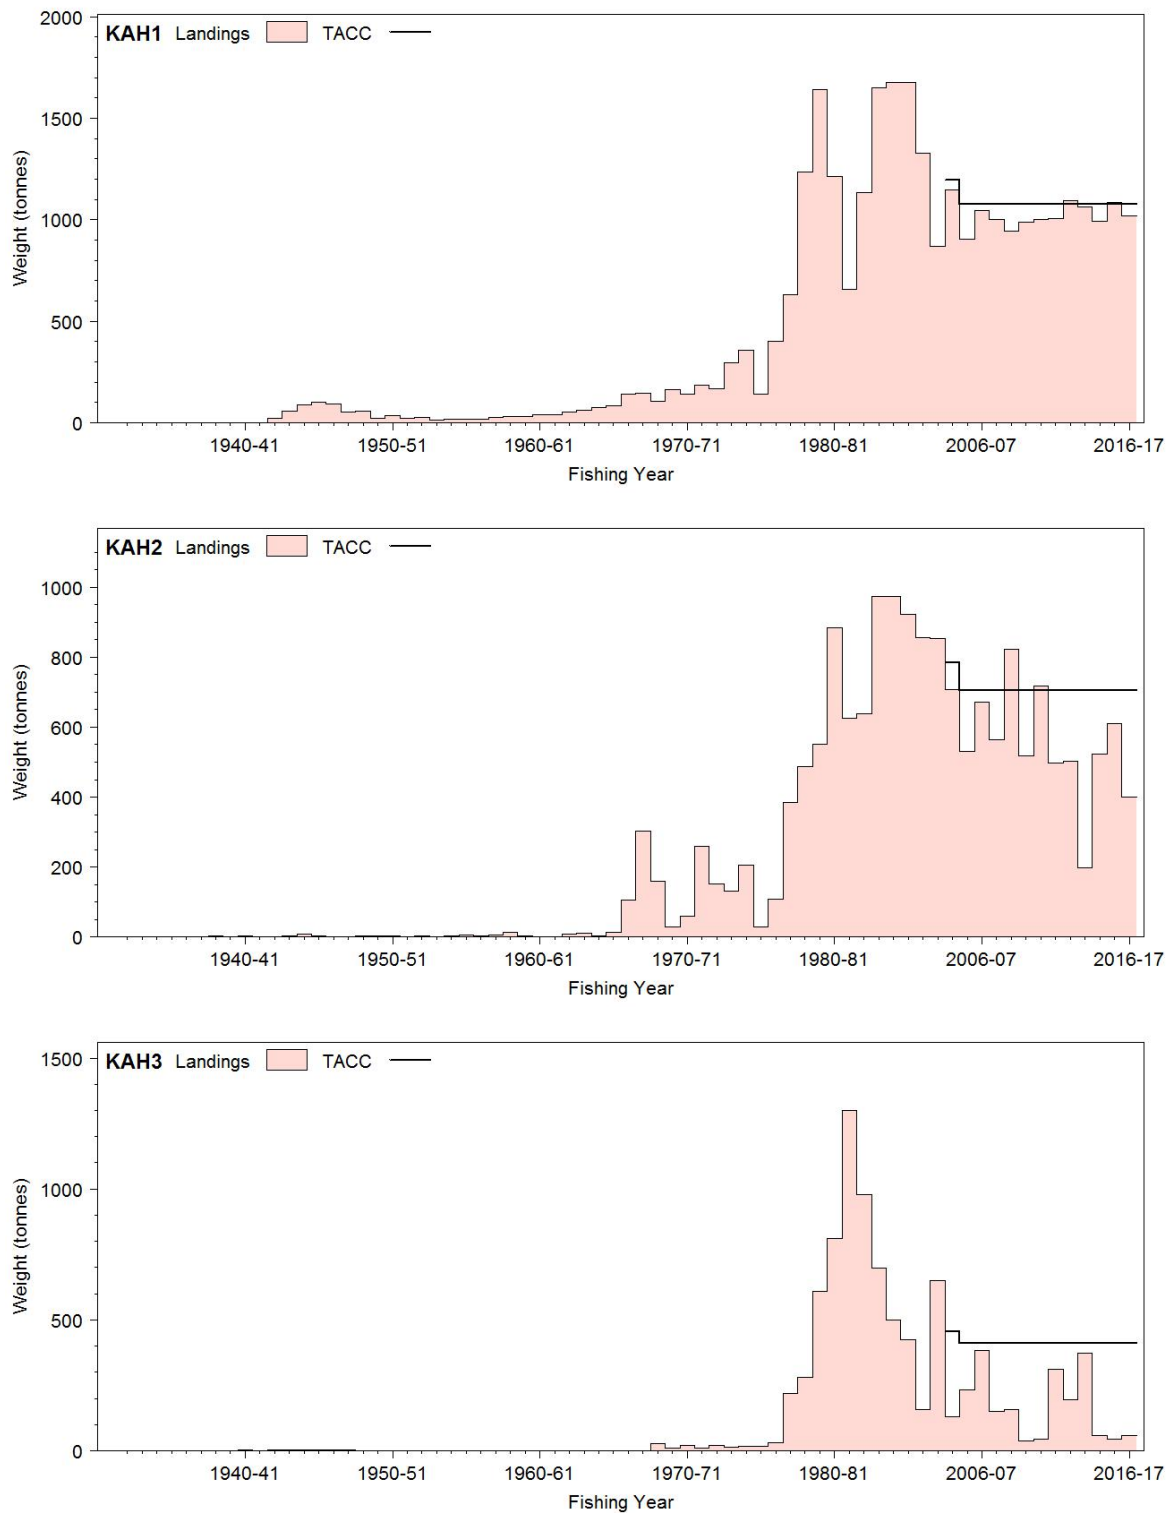

Figure 1: Total commercial landings and TACC for the four main KAH stocks. From top left to bottom right: KAH 1 (Auckland East), KAH 2 (Central East), KAH 3 (South East Coast, South East Chatham Rise, Sub-Antarctic, Southland, Challenger). [Continued on next page].

Figure 1: [Continued] Total commercial landings and TACC for the four main KAH stocks: KAH 8 (Central Egmont, Auckland West).

Since kahawai entered the Quota Management System on 1 October 2004, the purse seine catch limits no longer apply and landings, regardless of fishing method, are now restricted by quota availability and fishing company policies.

1.2 Recreational fisheries

Kahawai is the second most important recreational species in FMA 1 (after snapper). Kahawai are highly prized by many recreational fishers, who employ a range of shore and boat based fishing methods to target and/or catch the species. Kahawai is one of the fish species more frequently caught by recreational fishers, and recreational groups continue to express concern about the state of kahawai stocks in some areas. Historical kahawai recreational catches are poorly known. The current allowances within the TAC for each fishstock are shown in Table 1.

Information from the 2011–12 national panel survey (Wynne-Jones et al 2014) show that kahawai were mainly caught by rod or line (93.7%), with just over half of the landed catch taken from trailer boats (54.4%), and a third were taken off land.

1.2.1 Management controls

The main method used to manage recreational harvests of kahawai is the daily bag limit. The current limits for kahawai are: up to 20 kahawai within a multi-species bag limit of 20 fish in the Auckland, Kermadec, Central and Challenger management areas; up to 15 kahawai within a multi-species bag limit of 30 fish in the South-East, Southland and Fiordland management areas; and up to 10 kahawai within a multi-species bag limit of 30 fish in the Kaikoura management area. A minimum net mesh size applies in all areas (the mesh sizes do vary by management area and net type).

1.2.2 Harvest estimates

There are two broad approaches to estimating recreational fisheries harvest: the use of onsite or access point methods, where fishers are surveyed or counted at their fishing location, or at an access point when they return to land after their fishing trip; and offsite methods, where some form of post-event interview and/or diary are used to collect data from fishers.

The first estimates of recreational harvest for kahawai were generated using an offsite regional telephone and diary survey approach in: MAF Fisheries South (1991–92), Central (1992–93) and North (1993–94) regions (Teirney et al 1997). Estimates for 1996 came from a national telephone and diary survey (Bradford 1998). Another national telephone and diary survey was carried out in 2000 (Boyd & Reilly 2002) and a rolling replacement of diarists in 2001 (Boyd et al 2004) provided estimates for a further year (mean weights were not re-estimated in 2001). Other than for the 1991–92 MAF Fisheries South survey, the diary method used mean weights of kahawai obtained from fish measured at boat ramps.

The harvest estimates provided by telephone-diary surveys between 1993 and 2001 are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. This led to the development of an alternative maximum count aerial-access onsite method that provides a more direct means of estimating recreational harvests for boat based fisheries. The maximum count aerial-access approach combines data collected concurrently from two sources: a creel survey of recreational fishers returning to a subsample of ramps throughout the day; and an aerial survey count of vessels observed to be fishing at the approximate time of peak fishing effort on the same day. The ratio of the aerial count in a particular area relative to the number of interviewed parties who claimed to have fished in that area at the time of the overflight was used to scale up harvests observed at surveyed ramps, to estimate harvest taken by all fishers returning to all ramps (Hartill et al 2007b).

This aerial-access method was first used to estimate the recreational snapper harvest in the Hauraki Gulf in 2003–04 (Hartill et al 2007b), which was subsequently extended to survey the wider SNA 1 fishery in 2004–05 (Hartill et al 2007c). One benefit of this method is that it also provides harvest estimates for other key species, in particular kahawai (Table 8). The Marine Amateur Fisheries Working Group has concluded that this approach generally provides broadly reliable estimates of recreational harvest for KAH 1. It is not, however, possible to reliably quantify shore based fishing from the air and it is necessary to derive scalars from offsite surveys to account for the shore-based kahawai catch. Aerial-access surveys, focusing on snapper, have provided kahawai harvest estimates for the Hauraki Gulf in 2003–04 and for all of FMA 1 in 2004–05 and 2011–12. The most recent aerial-access survey was conducted in FMA 1 in 2011–12 (Hartill et al 2013), to independently provide harvest estimates for comparison with those generated from a concurrent national panel survey.

In response to problems with previous telephone-diary surveys and the cost and scale challenges associated with onsite methods, a National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. The two 2011–12 surveys appear to provide plausible results that corroborate each other for KAH 1, and are therefore considered to be broadly reliable (Hartill et al 2013).

Recreational harvest estimates from offsite surveys up to and including 2011–12 are given in Table 7 (from Wynne-Jones et al 2014 and Hartill & Davey 2015), noting that the QMAs do not all match up with the strata used for the older harvest estimates (in particular for KAH 3 and 8). A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.2.3 Monitoring harvest

In addition to estimating absolute harvests, a system to provide relative estimates of harvest over time for key fishstocks has been designed and implemented for some key recreational fisheries. The system uses web cameras to continuously monitor trends in trailer boat traffic at key boat ramps complemented by creel surveys that provide estimates of the proportion of observed boats that were used for fishing and the average harvest of snapper and kahawai per boat trip. These data are combined to provide relative harvest estimates for KAH 1 (Table 9). Differences between aerial-access harvest estimates in the Hauraki Gulf in 2004–05 and in 2011–12 are of a similar magnitude to those inferred from the web cameras index, which suggests that web camera based relative harvest indices are reasonably robust. The web camera/creel index suggests that the recreational kahawai in the Hauraki Gulf decreased by over 50% between 2011–12 and 2012–13 but has fluctuated without apparent trend since. In East Northland, the catch decreased by over 50% between 2012–13 and 2014–15, but then doubled by 2016–17. In the Bay of Plenty the trend is generally flat other than for a much larger catch in 2015–16. Across the whole of KAH 1, the total harvest fell by over 50% between 2011–12 and 2014–15 but has increased again since. These estimates show the variability of recreational harvests between years and, in particular, that harvest levels can be driven not only by abundance but also by changes in localised availability.

KAHAWAI (KAH)

Table 7: Recreational catch estimates for kahawai stocks. The surveys ran from October or December through to September or November but are denoted by the January calendar year. Mean fish weights were obtained from boat ramp surveys (for the telephone/diary and panel survey catch estimates).

¹ Mean weight obtained from 1992–93 boat ramp sampling.

² The 2000 mean weights were used in the 2001 estimates.

³ Separate mean weight estimates were used for summer (1 October 2011 to 30 April 2012) and for winter (1 May to 30 September 2012).

⁴ Separate mean weight estimates were used for the eastern and western Bay of Plenty.

⁵ Temporally and spatially separate mean weight estimates used as per notes 3 and 4.

⁶ No harvest estimate available in the survey report, estimate presented is calculated as average fish weight for all years and areas by the number of fish estimated caught.

Table 8: Summary of kahawai harvest estimates (t) derived from an aerial overflight survey of the Hauraki Gulf in 2003–04 (1 December 2003 to 30 November 2004; Hartill et al 2007b) and a similar KAH 1 wide surveys conducted in 2004–05 (1 December 2004 to 30 November 2005; Hartill et al 2007c) and in 2011–12 (1 October 2011 to 30 November 2012; Hartill et al 2013). Values in brackets denote CVs associated with each estimate.

Year	East Northland	Hauraki Gulf	Bay of Plenty	KAH 1
2003–04	-	56 (0.15)	-	-
2004–05	129 (0.14)	98 (0.18)	303 (0.14)	530 (0.09)
2011–12	191 (0.16)	483 (0.13)	268 (0.12)	942 (0.08)

Table 9: Recreational catch estimates (t) for kahawai in different parts of the KAH 1 stock area calculated from web camera and creel monitoring at key ramps combined with aerial-access estimates for each area in 2004–05 and 2006–07 (Hauraki Gulf only) and 20011–12 (all areas within KAH 1). Unpublished data from project MAF2014-04.

Web camera and creel monitoring has commenced in other kahawai QMAs but the results cannot yet be used to infer trends in those fisheries.

1.3 Customary non-commercial fisheries

Kahawai is an important traditional and customary food fish for Maori. The level of customary catch has not been quantified and an estimate of the current customary non-commercial catch is not available. Some Maori have expressed concern over the state of their traditional fisheries for kahawai, especially around the river mouths in the eastern Bay of Plenty.

1.4 Illegal catch

Estimates of illegal catch are not available, but are probably insignificant.

1.5 Other sources of mortality

There is no information on other sources of mortality. Juvenile kahawai may suffer from habitat degradation due to run-off, siltation and loss of shelter in estuarine areas.

2. BIOLOGY

Kahawai (*Arripis trutta*) are a schooling pelagic species belonging to the family Arripidae. Kahawai are found around the North Island, the South Island, the Kermadec and Chatham Islands. They occur mainly in coastal seas, harbours and estuaries and will enter the brackish water sections of rivers. A second species, *A. xylabion*, has been described (Paulin 1993). It is known to occur in the northern EEZ, at the Kermadec Islands and seasonally around Northland.

Kahawai feed mainly on fishes but also on pelagic crustaceans, especially krill (*Nyctiphanes australis*). Kahawai smaller than 100 mm mainly eat copepods. Although kahawai are principally pelagic feeders, they will take food from the seabed.

The spawning habitat of kahawai is unknown but is thought to be associated with the seabed offshore. Schools of females with running ripe ovaries have been caught by bottom trawl in 60–100 m in Hawke Bay (Jones et al 1992). Other females with running ripe ovaries have been observed in east coast purse seine landings sampled in March and April 1992, and between January and April in 1993 (McKenzie NIWA, unpublished data). Length-maturation data collected from thousands of samples in the early 1990s suggest that the onset of sexual maturity in males occurs at around 39 cm (fork length) and in females at 40 cm (McKenzie NIWA, unpublished data). This closely matches an estimate of 39

KAHAWAI (KAH)

cm used for Australian *A. trutta* (Morton et al 2005). This length roughly corresponds to fish of four years of age in both countries. Eggs have been found in February in the outer Hauraki Gulf. Juvenile fish (0+ year class) can be found in shallow water over eelgrass meadows (*Zostera* spp.) and in estuaries.

Kahawai are usually aged using otoliths, following an ageing technique that has been validated (Stevens & Kalish 1998). Kahawai grow rapidly, attaining a length of around 15 cm at the end of their first year, and maturing after 3–5 years at about 35–40 cm, after which their growth rate slows. The longest recorded *A. trutta* had a fork length of 79 cm and was caught by a recreational fisher in the Waitangi Estuary, in Hawke Bay in August 1997 (Duffy & Petherick 1999). Northern kahawai, *Arripis xylabion*, grow considerably bigger than kahawai and attain a maximum length of at least 94 cm, but beyond this, little is known about the biology of *A. xylabion*. Male and female von Bertalanffy growth curves appear to be broadly similar, with females attaining a slightly higher value for L_{∞} , although statistical comparison of sex specific curves using a likelihood ratio test (Kimura 1980) suggests that they are statistically different (Hartill & Walsh 2005). Combined-sex growth curves are probably adequate for modelling purposes and are provided for some areas in Table 10. Sex specific growth parameters given for KAH 1 in previous plenary documents have higher estimates for L_{∞} (56.93 for males and 55.61 for females).

The maximum recorded age of kahawai is 26 years and this age has been previously used to estimate the instantaneous rate of natural mortality (M) using the equation $M = \log_e 100 / \text{maximum age}$ (Jones et al 1992). The resulting estimate of M of 0.18 assumes that this maximum observed age equates to that at which 1% of the population would survive in an unexploited stock, but a higher value for M is now considered more likely. This is because a reanalysis of purse seine catch-at-age data collected by Eggleston from KAH 2 & 3 between 1973 and 1975 suggests that 1% of the unexploited population would have lived for 20 years, which equates to an M of 0.23. A Chapman-Robson estimate of M of 0.22 was also derived from these catch-at-age data. Estimates of M ranging from 0.18 to 0.23 were therefore considered in the 2015 stock assessment and the assumed value used in the base case model was 0.20

Table 10: Estimates of biological parameters.

Fishstock		Estimate		Source

KAH 9	0.23	-0.26	55.9	McKenzie, NIWA, unpubl. data

3. STOCKS AND AREAS

Kahawai are presently defined as separate units for the purpose of fisheries management: KAH 1 (FMA 1); KAH 2 (FMA 2); KAH 3 (FMAs 3, 5, 6 & 7); KAH 4 (QMA 4); KAH 8 (FMAs 8 & 9) and KAH 10 (FMA 10).

Returns from tagging programmes do not provide definitive information on the level of potential mixing between KAH QMAs, but tagging returns suggest that most kahawai (*A. trutta*) remain in the same area for several years, but some move throughout the kahawai habitat. The pattern of kahawai movement around New Zealand is poorly understood and there are regional differences in age structure and abundance that are consistent with limited mixing between regions.

Smith et al (2008) compared otolith micro-chemistry (multi-element chemistry and stable isotopes) and meristics (e.g., fin counts) from 0-group kahawai from two regions (Okahu Bay, Waitemata Harbour and Hakahaka Bay, Port Underwood). Two distant sites were chosen in order to provide the best chance of successful discrimination. Neither meristics nor stable isotopes provided any discrimination and magnesium and barium concentrations provided only weak discriminatory power.

On balance it seems possible that there are least two stocks of kahawai (*A. trutta*) within New Zealand waters with centres of concentration around the Bay of Plenty and the northern tip of the South Island. These two areas could be assumed to be separate for management purposes. Tagging data show that there is some limited mixing between these areas. Due to the shared QMA boundaries in the lower North Island and South Island, there is likely to be more mixing between the southern KAH QMAs than with the northern QMA (KAH 1).

There is no information about stock structure of *A. xylabion*.

4. STOCK ASSESSMENT

An age-structured assessment of the KAH 1 stock was first undertaken in 2007 (Hartill 2009), and was updated and revised in 2015 (Hartill & Bian 2016). Both assessments were undertaken using CASAL (Bull et al 2004). This assessment is reported below.

There are no accepted assessments for kahawai stocks outside of KAH 1, although there are some catch curve estimates of Z from these areas from the early 1990s, which are reported here.

4.1 KAH 1

4.1.1 Estimates of catch, selectivity and abundance indices

(i) Commercial catch

The commercial catch history used in the assessment is provided in Table 11. Annual catch by method landings statistics up until 1981–82 were provided by Francis & Paul (2013), and Fisheries Statistics Unit data were used to generate landings statistics for the period 1982–83 to 1988–89. It is noted that catches during these early years are less certain due to reporting issues (e.g. see Table 4 legend).

Table 11: Commercial catch time series used in the 2015 stock assessment of KAH 1.

(ii) Recreational catch

The recreational catch history in KAH 1 is poorly known. Aerial overflight estimates are available for the Hauraki Gulf in 2003–04 (Hartill et al 2007b) and for all three regions of KAH 1 in 2004–05 (Hartill et al 2007c) and in 2011–12 (Hartill et al 2013). Recreational harvest estimates for all three regions of KAH 1 are also available from a National Panel Survey undertaken in 2011–12 (Wynne-Jones et al 2014), which were of a similar magnitude to those provided by the aerial-access survey.

Levels of recreational harvesting vary from year to year, however, and the aerial-overflight estimates were therefore used to scale up regional catch per trip (landed catch weight per hour fished) indices derived from creel surveys conducted since 1990, to gauge likely levels of harvesting taking place across a wider range of years (Figure 2). The coefficient used to scale up the catch rate index in each region was the geometric mean of the aerial overflight estimates divided by the geometric mean of catch index during the aerial overflight survey years. The 2011–12 aerial overflight estimate was not used to inform the Bay of Plenty recreational catch history because the closure of waters of around Motiti Island following the grounding of the M.V. *Rena* in early October 2011, would have reduced levels of recreational catch and effort in an atypical fashion. The constant catch history estimates given in Figure 2 were used to inform regional constant catch histories for the period 1974–75 to 2012–13.

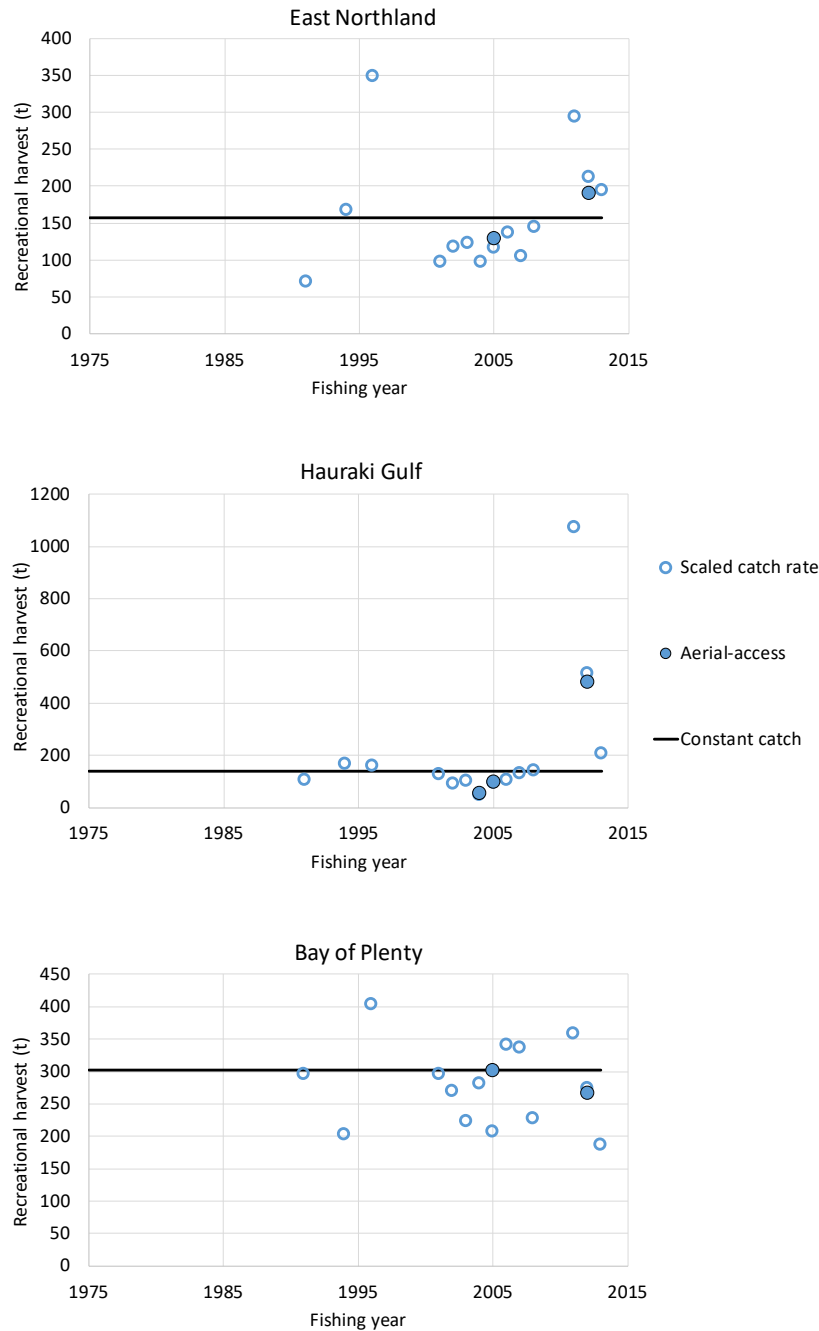

Figure 2: Regional recreational catch histories based on estimates provided by recent aerial-access surveys in 2004–05 and 2011–12. The 2011–12 estimate for the Bay of Plenty was not used as harvests in this year may have been adversely affected by the grounding of the M.V. *Rena*.

Constant harvest tonnages were used as there was concern that if a catch history with an assumed trend was used, this trend could influence the model results, despite being essentially unknown. Estimates of recreational harvest were required back to 1930–31, however, and the harvest at that time was assumed to be 10% of that in 1974–75, which was then ramped up to that value over the intervening years. These regional catch histories were then combined into a single catch history for KAH 1, which is assumed to include harvests taken by customary fishers (Figure 3).

Figure 3: Recreational catch history for KAH 1 from 1931 to current that was assumed in the 2015 assessment.

(iii) Catch composition data and selectivity estimates

The earliest catch-at-age data that are available were collected from single trawl and purse seine landings sampled in 1991, 1992 and 1993. Purse seine landings were also sampled in 2005, 2011 and 2012. Catch-at-age data were available from set net landings from the Hauraki Gulf in 2011 and 2012, which were sampled so that the selectivity for this method could be estimated.

Recreational landings sampled during 10 years between 2001 and 2012 provided the most consistently sampled source of catch-at-age data used in the assessment (Hartill et al 2007a, 2007d, 2008, Armiger et al 2006, 2009, 2014). Boat ramp surveys were conducted in East Northland, the Hauraki Gulf, and the Bay of Plenty between January and April in each year. Annual catch-at-age distributions for each of the three regions were weighted together given the assumed catch history for each region, to provide a single time series for KAH 1 for this fishery.

All composition data were iteratively reweighted following the Francis method, which resulted in effective sample sizes being down weighted by about 98% for the recreational and purse seine catch-at-age data and by 85% of the single trawl data. This process maintained CVs for the abundance indices at the level originally estimated outside of the model.

Logistic selectivity ogives were estimated for the purse seine, single trawl and recreational fisheries, and the single trawl ogive was also used when accounting for the relatively small tonnage landed by other methods such as Danish seine and beach seine. A double normal selectivity was estimated from the set net catch-at-age data and subsequently fixed at MPD parameter values.

(iv) Indices of abundance

Three indices of abundance were available for the assessment, but only two of these were ultimately offered to the model. Both a recreational CPUE and an aerial Sightings per Unit Effort (SPUE) were considered informative, but the set net CPUE index used in the 2007 assessment was no longer considered reliable because ring net fishing is often reported as set net fishing.

Recreational CPUE index

The recreational CPUE index used in the model was based on creel survey data collected at boat ramps during surveys conducted intermittently since 1991. Creel survey data were only used from East Northland and the Bay of Plenty, as catch rates in the Hauraki Gulf in about 2008 increased as a result of an influx of large kahawai, reflecting localised availability rather than abundance.

Separate CPUE (kg/hr) indices were initially calculated for East Northland and the Bay of Plenty, which were then weighted together based on the relative harvest taken from these regions, to provide a single abundance index for the KAH 1 stock. These indices were calculated from data collected between

January and April only, as few surveys were conducted at other times of the year. Rod and line catch rate data were used from a core set of ramps only, which were surveyed in all past surveys.

Attempts were made to generate a standardised index but very few variables were available to inform any standardisation, especially as neither fisher nor vessel identifiers are recorded during creel surveys. The first term selected by any of the standardisations attempted was always fishing year, and remaining terms such as fishing location and month were often not selected or had little effect on the indices produced. The recreational CPUE index used in this assessment was therefore unstandardized (Figure 4).

Figure 4: Unstandardised recreational CPUE (kg/hr). Vertical lines are bootstrap 95% confidence intervals.

Aerial sightings index

In 2012, an index of abundance [sightings per unit effort (SPUE)] based on commercial aerial sightings data was accepted by the Northern Inshore Working Group. This index was calculated using data from the *aer_sight* database and applying a generalised additive model (GAM) to produce standardised annual relative abundance indices (Taylor 2014).

Flights were restricted to those that were exclusive to the Bay of Plenty (BoP) (i.e., those having flight paths that remained within an area defined as the BoP), only flown by pilot #2 and were the first flight of the day (apart from some defined exceptions, e.g., short refuelling flights at the start of the day).

Estimates of relative year effects were obtained using a forward stepwise GAM, where the data were fitted using two models: 1) the probability of a flight having a positive sighting modelled using a binomial regression; and 2) the tonnage sighted on positive flights modelled using a lognormal regression. These two models were combined into a single index. The data used for the SPUE analyses consisted of aerial sightings of kahawai, trevally, jack mackerel, blue mackerel, and skipjack tuna collected over the period 1986–87 to 2010–11, with missing years in 1988–89, from 1994–95 to 1996–97 and in 2006–07. Most of these missing years were the result of there being no available data. By contrast, 2006–07 was dropped because the working group identified a bias in the annual index for that year because of the low number of available flights. The first year of the original series (1985–86) was dropped by the working group for the same reason.

The species with the maximum daily purse-seine catch from the vessels that the pilot was working in the BoP was used as a proxy for target species. Catch data before 1989 were from the *fsu-new* database and data from 1989 to 2013 were from the *warehou* database.

KAHAWAI (KAH)

Table 12: Standardised sightings per unit effort (SPUE) indices for the Bay of Plenty KAH 1 stock, derived as a combination of year effect estimates from a lognormal and a binomial regression for the period 1986–87 to 2012–13.

Fishing year	Combined	CV
1986–87	1.14	0.31

Figure 5: Standardised sightings per unit effort (SPUE) indices for the Bay of Plenty KAH 1 stock, derived as a combination of year effect estimates from a lognormal and a binomial regression. Vertical lines are 95% confidence intervals.

The Working Group accepted the combined model of SPUE for kahawai as an index of abundance in the BoP. The BoP combined SPUE index for kahawai shows substantial inter-annual variation with an overall gradual declining trend from 1986–87 to 2002–03; thereafter increasing sharply to a peak in 2007–08, and then declining to points above the long-term mean (Table 12, Figure 5).

4.1.2 Model structure

The stock assessment was restricted to KAH 1, because this is the QMA where most of the observational data have been collected. Future assessments may consider a broader stock definition, but improved understanding of the movement dynamics of this species and further development of this model are required before this can be attempted. Even within KAH 1 there is little information on connectivity between the three main areas of the fishery: East Northland, Hauraki Gulf and the Bay of Plenty. There are few tag data available that can be used to estimate these migration processes, because almost all of the kahawai that have been tagged have been released in the Bay of Plenty. This provides little information about emigration from the Hauraki Gulf and from East Northland. Recreational catch-at-age data collected since the 2007 assessment now suggest that size based migration between areas may vary more considerably and unpredictably than previously thought. For these reasons, the data used in the assessment were no longer regionally partitioned, but were combined into a single stock model which includes most of the currently available data.

In the stock assessment model it is assumed that KAH 1 is a single biological stock, exploited by several fisheries. Deviations from the spawner recruitment curve were estimated for those years when there were three or more years of observational catch-at-age data, and were constrained to a mean of 1.0 across all fishing years from 1974–75 to 2012–13.

A single annual time step was used, in which ageing was followed by recruitment, maturation, growth, and then mortality (natural and fishing). The relationships between length and age, and length and weight, were both assumed to be constant through time and were based on updated parameter values given in Table 10. Annual abundances of the age classes 1 to 20 were estimated in the model, with 20 year olds representing all fish older than 19 years. The model was not sex specific. Maturation was knife edged at four years of age. There is no information on the relationship between stock size and recruitment, and the rate of natural mortality is uncertain. Sensitivity to these parameters is discussed in the next section.

It was assumed that the population was at an unfished equilibrium state (B_0) in 1930, as reported commercial landings between 1930 and 1940 were only in the order of 1 to 2 tonnes per year. Key model outputs are probably robust to this assumption as commercial landings were only of the order of a few hundred tonnes and recreational landings were assumed to be low relative to stock size prior to this time. Total fishing mortality was apportioned between fisheries according to observed catches and estimated selectivities. Method specific annual landings from five fishing methods were considered: recreational, purse seine, single trawl, set net, and other minor commercial fisheries.

4.1.3 Evaluation of uncertainty

Evaluations of preliminary models identified three sources of uncertainty which were subsequently investigated in more detail: the assumed value for natural mortality (M); choice of abundance index; and the assumed steepness (h) of the Beverton-Holt stock recruitment relationship.

Alternative values of steepness of 0.75 and 0.90 appeared to have little influence on either current biomass or stock status, as sensitivity model runs suggested the spawning stock biomass has never fallen to low enough levels for this to have an effect. A base case value of 0.75 was assumed for all subsequent model runs.

An M of 0.20 was assumed for the base case model, in which both the SPUE and Recreational CPUE were considered. Three sensitivity models were also considered: two with alternative M estimates (0.18 and 0.23), and another where M was assumed to be 0.20, but only the recreational CPUE index was offered to the model (i.e. the SPUE index was omitted).

MCMCs were run for all four of these models. However, the $M = 0.23$ sensitivity model performed poorly despite an extended burn in period of 2 million iterations. MCMC traces for some parameters fluctuated markedly and the run terminated as it approached its 4 millionth iteration. This model was rejected due to the lack of convergence and results are not reported here.

The three remaining models were projected for a five year period (2014 to 2019), with future catches for each fishing year being set to those in 2012–13. Year class strengths were drawn from the 10-year period, 2000–2009.

4.1.4 Results

All of the models suggested that the stock was gradually fished down until the late 1970s, followed by a steeper decline that coincided with the development of the purse seine fishery during the 1980s. There have since been marked fluctuations in stock size but there is general evidence of a rebuild since the early 2000s.

The assumed value for M had the greatest influence on the model results, with the base case of $M = 0.2$ producing higher stock biomass and stock status (Figure 6). The lower value of 0.18 resulted in lower biomass estimates and lower current stock status when both abundance indices were offered to the model. Dropping the SPUE index suggested there had been less of a rebuild since the early 1990s, but there was still evidence of an increase in spawning stock biomass in recent years.

Figure 6: Comparison of spawning stock biomass (upper panel) and stock status trajectories (lower panel) for the base case (where M was assumed to be 0.20 and both the recreational CPUE and SPUE indices were offered to the model) and for two other sensitivities. The vertical dashed line denotes first year of the projection period (2014).

All three model runs suggest that the KAH 1 stock has never fallen below about 40% B_0 (Figure 6). Median % B_0 in 2013 was estimated to be 66% for the base case, 56% for the case with lower M and 58% when the SPUE was excluded (Table 13). In 2010 the Minister of Fisheries set a target reference point of 52% B_0 for this shared fishery, and although two of the sensitivity runs suggest that the KAH 1 stock biomass has fallen below this level at times, there is a high probability that the current biomass predicted by each model is well above this level (Table 13).

Table 13: Biomass and stock status estimates derived from MCMC runs for the base model (M_20_both; three chains combined) and two sensitivity models (medians with 95% credible intervals in parentheses).

Model	SSB_0	SSB_{2013}	$SSB_{52\%}$	SSB_{2013}/SSB_0	$SSB_{2013}/SSB_{52\%}$
M20_both	48 888	31 889	25 225	0.663	1.275
(Base case)	(38 973–92 822)	(20 334–79 232)	(20 266–48 267)	(0.521–0.854)	(1.000–1.641)
M18_both	44 340	24 952	17 736	0.563	1.407
	(38 536–56 991)	(17 250–39 700)	(15 414–22 796)	(0.448–0.697)	(1.119–1.7415)
M20_rec	41 569	23 933	16 628	0.576	1.439
	(38 305–46 362)	(20 054–29 511)	(15 322–18 545)	(0.524–0.637)	(1.309–1.591)

Figure 7: Spawning stock biomass relative to B_0 for the base model ($M = 0.20$, both abundance indices used; three chains combined). The 52% B_0 target set by the Minister of Fisheries in 2010 is denoted by a black dashed line and the 20% B_0 soft limit is denoted by the grey dashed line. The grey shaded area denotes 95% credible intervals derived from the MCMC model run and the black line denotes the median estimate for each year. The vertical dashed line denotes the first year of the projection period (2014).

Table 14: Probability of the KAH 1 stock in 2013 falling below soft and hard limits and being at or above the target reference point. The target reference point of 52% B_0 was set by the Minister of Fisheries for this stock in 2010. Probabilities are calculated from the distribution of MCMC estimates calculated from each model.

Model	$\Pr(SSB_{2013} < 10\% SSB_0)$	$\Pr(SSB_{2013} < 20\% SSB_0)$	$\Pr(SSB_{2013} > 52\% SSB_0)$
M20_both	0.000	0.000	0.975
M18_both	0.000	0.000	0.738
M20_rec	0.000	0.000	0.755

4.1.5 Projections and yield estimates

The base and sensitivity models were projected forward five years, with empirical resampling from the 10-year period, 2000–2009, using the reported 2013 catch. These projections suggest that current stock status is likely to improve further under all three scenarios, with a faster level of increase seen in the less optimistic lower M scenario. The probability of the stock being at or above 52% B_0 in 2018 is 0.945 for the base case.

Table 15: Probability of the KAH 1 stock in 2018 falling below soft and hard limits and being at or above the target reference point. The target reference point of 52% B_0 was set by the Minister of Fisheries for this stock in 2010. Probabilities are calculated from the distribution of MCMC estimates calculated from each model (three chains combined for the base model).

Model	SSB_{2018}/SSB_0	$\Pr(SSB_{2018} < 10\% SSB_0)$	$\Pr(SSB_{2018} < 20\% SSB_0)$	$\Pr(SSB_{2018} > 52\% SSB_0)$
M20_both	0.693 (0.629–0.742)	0.000	0.000	0.940
M18_both	0.596 (0.563–0.648)	0.000	0.000	0.756
M20_rec	0.620 (0.557–0.673)	0.000	0.000	0.755

The deterministic yield corresponding to 52% B_0 from the base case model is 2 414 t.

4.1.6 Catch-curve analysis

Annual estimates of total mortality (Z) have also been derived from recreational catch data sampled in East Northland and the Bay of Plenty. They were calculated using a Chapman Robson estimator independently from the stock assessment model (Table 16). These estimates were calculated using a range of assumed ages for full recruitment to demonstrate the sensitivity of the results to this assumption.

Table 16: Estimates of Z derived from recreational catch sampling in KAH 1, by survey year by assumed age at recruitment (from Armiger et al 2014).

Area	Year										East Northland	
	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012
3	0.33	0.33	0.32	0.28	0.24	0.23	0.28	0.24	-	-	0.20	0.21
4	0.34	0.38	0.35	0.31	0.28	0.26	0.32	0.28	-	-	0.23	0.22
5	0.30	0.37	0.39	0.33	0.33	0.32	0.35	0.33	-	-	0.27	0.25
6	0.30	0.40	0.41	0.38	0.36	0.36	0.41	0.34	-	-	0.32	0.28

Area	Year										Bay of Plenty	
	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012
3	0.23	0.25	0.28	0.20	0.27	0.25	0.24	0.24	-	-	0.20	0.23
4	0.26	0.30	0.32	0.23	0.29	0.30	0.27	0.27	-	-	0.23	0.26
5	0.28	0.33	0.34	0.26	0.30	0.30	0.24	0.29	-	-	0.26	0.29
6	0.30	0.36	0.38	0.32	0.30	0.32	0.26	0.29	-	-	0.31	0.31

4.1.7 Future research needs

- Otoliths from the Hauraki Gulf should be collected in future recreational catch-at-age creel surveys so that they are available for reading if required, as this was not done in 2011 and 2012.
- A spatial model should be considered for the next assessment if there are data to inform it on movements of different age/size classes between sub-areas. This may reduce the patterns in residuals for model fits to recreational catch at age.

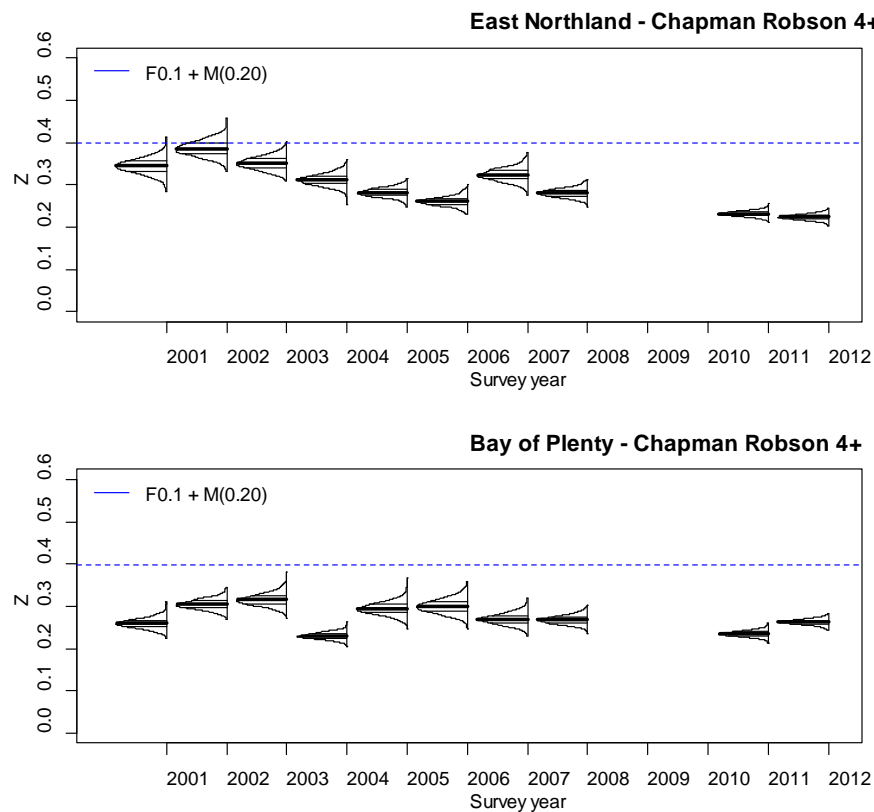

Figure 8: The distribution of bootstrap Chapman Robson estimates of total mortality (Z) by survey year for East Northland (top panel) and the Bay of Plenty (lower panel). A theoretical optimal level of Z derived from a YPR curved generated from the 2015 assessment is denoted as a horizontal line for reference purposes (adapted from Armiger et al 2014).

5. STATUS OF THE STOCKS

KAH 1

Stock Structure Assumptions

Two stocks of kahawai (*A. trutta*) are assumed to exist within New Zealand waters with centres of concentration around the Bay of Plenty and the northern tip of the South Island. Tagging data show that there is limited mixing between these areas.

Stock Status	
Year of Most Recent Assessment	2015: Age based stock assessment
Assessment Runs Presented	Base case model with $M=0.2$ and two abundance indices (recreational CPUE and aerial sightings)
Reference Points	Target: 52% B_0 (set by Minister of Fisheries in 2010) Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{35\%B_0}$
Status in relation to Target	Very Likely (> 90%) to be at or above
Status in relation to Limits	Soft Limit: Very Unlikely (< 10%) to be below. Hard Limit: Exceptionally Unlikely (< 1%) to be below
Status in relation to Overfishing	Overfishing is Very Unlikely (<10%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory of spawning stock biomass relative to B_0 for the base model ($M = 0.20$, both abundance indices used) and annual fishing intensity. The 52% B_0 target set by the Minister of Fisheries in 2010 is denoted by a black dashed line and the 20% B_0 soft limit and 10% B_0 hard limit are denoted by the grey dashed lines.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Stock biomass has increased in recent years.
Recent Trend in Fishing Mortality or Proxy	Fishing mortality has declined since the early 1990s and is now well below the overfishing threshold.
Other Abundance Indices	None available other than regional set net CPUE indices which are not considered to be reliable because of confusion between set net and ring net effort reporting.
Trends in Other Relevant Indicators or Variables	- A time series of total mortality estimates for East Northland and the Bay of Plenty from 2001 to 2012, based on recreational catch-at-age data, suggests that there has been little change in fishing mortality over this period. Estimates of total mortality were at or below that associated with $F_{0.1}$ suggesting that fishing mortality was at or below F_{MSY} .

Projections and Prognosis

Stock Projections or Prognosis	The KAH 1 stock is likely to increase over the next five years at 2013 catch levels.
Probability of Current Catch or TAC causing biomass to remain below or to decline below Limits	Soft Limit: Very Unlikely (< 10%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of current catch or TAC causing overfishing to continue or to commence	Exceptionally Unlikely (< 1%)

Assessment Methodology and Evaluation

Assessment Type	Level 1 – Full Quantitative Stock Assessment	
Assessment Method	Statistical catch at age model implemented under CASAL	
Assessment Dates	Latest assessment: 2015	Next assessment: 2020
Overall assessment quality rank	1 – High Quality	

Main data inputs (rank)	<ul style="list-style-type: none"> - Proportions-at-age from purse seine, single trawl, set net and recreational fisheries - Unstandardised recreational CPUE index - Estimates of biological parameters (e.g. growth, age-at-maturity, length/weight) - Estimates of recreational harvest - Commercial catch statistics - Aerial SPUE index 	<p>1 – High Quality: but set net data were only used to estimate MPD selectivity</p> <p>1 – High Quality</p> <p>1 – High Quality</p> <p>1 – High Quality</p> <p>1 – High Quality</p> <p>2 – Medium or Mixed Quality: only covers western Bay of Plenty</p>
Data not used (rank)	- Set net CPUE indices	3 – Low Quality: confusion between set net and ring net fishing reporting
Changes to Model Structure and Assumptions	<ul style="list-style-type: none"> -Change from grid to age structured base case with MCMC -Change from quasi regional to single stock structure -Dropped set net CPUE -Included age composition for set net catch -Included SPUE -Started model in 1930 at equilibrium instead of 1975 -Changed default M from 0.18 to 0.20 	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Under-reported commercial catch prior to 1980 - Recreational catch history, especially prior to 1990 - Assumption of constant selectivity and catchability in the abundance indices may compromise their ability to index biomass - Spatial complexity in the movement of different sizes/ages of kahawai - Age composition and selectivity of purse seine unlikely to be consistent from year to year due to kahawai schooling by age/size 	

Qualifying Comments

-

Fishery Interactions

Commercial catches of KAH 1 are primarily taken by purse-seine in association with jack mackerel, blue mackerel and trevally. Interactions with other species are currently being characterised.
--

All other KAH regions

No accepted assessment is available that covers these regions. It is not known if the current catches, allowances or TACCs are sustainable. The status of KAH 2, 3 and 8 relative to B_{MSY} is unknown.

KINA (SUR)*(Evechinus chloroticus)*

Kina

**1. FISHERY SUMMARY**

South Island kina was introduced into the Quota Management System in October 2002. North Island kina was introduced into the Quota Management System from October 2003. Five Quota Management Areas based on the FMAs 3, 4, 5, 7A (Marlborough Sounds) and 7B (west coast) were created in the South Island, and current allowances, TACCs, and TACs are summarised in Table 1. Seven Quota Management Areas based on the FMAs 1A (Auckland-North), 1B (Auckland-South), 2A (Central (East-North)), 2B (Central (East-South)), 8, 9 and 10 were created in the North Island, and the current allowances, TACCs and TACs are summarised in Table 2. The historical landings and TACC values for the main SUR stocks are depicted in Figure 1.

Table 1: Recreational and customary non-commercial allowances, TACCs and TACs (t) for kina Fishstocks 3, 4, 5, and 7 for the latest fishing year.

Fishstock	Recreational Allowance	Customary non-commercial Allowance	Other Mortality Allowance	TACC	TAC
SUR 3	10	10	1	21	42
SUR 4	7	20	3	225	255
SUR 5	10	10	5	455	480
SUR 7A	20	80	3	135	238
SUR 7B	5	10	1	10	26

Table 2: Recreational and customary non-commercial allowances, TACCs and TACs (t) for kina Fishstocks 1,2,8,9 and 10 for the latest fishing year.

1.1 Commercial fisheries

Most kina are found in waters less than 10 m deep and are harvested by breath-hold diving, although about 10% of the total catch in 1998–99 was by taken by dredge in SUR 7. Some target dredging also occurs in SUR 7. There is no minimum legal size for kina. Almost all of the roe harvested in this fishery is consumed on the domestic market. In 1988–89, competitive TACCs were established in the more important FMAs but not in east Northland (SUR 1) or at the Chatham Islands (SUR 4), both of which developed into productive fisheries in the 1990s (Table 3). On 1 October 1992 the Ministry of Fisheries placed a moratorium on the issue of permits to commercially harvest kina. The kina fishery has evolved considerably since the imposition of the moratorium. Where present, the competitive TACCs were either not caught or were exceeded, both by wide margins. Much of the increase in catch observed in SUR 5 in the early 1990s can be attributed to an experimental fishery developed in SUR 5, between Puysegur Point and Breaksea Island. The short-lived Kina Development Programme harvested kina from Dusky Sound in 1993 under special permit.

Table 3: Total reported catch (t greenweight) of kina (SUR) by FMA and fishing year by all methods and target species.

Year	SUR 1	SUR 1A	SUR 1B	SUR 2	SUR 2A	SUR 2B	SUR 3	SUR 4	SUR 5	SUR 6, 8, & 9	SUR 7	SUR 7A	SUR 7B	Total

Data from 1989 and 1990 are combined from the FSU and CELR databases. – indicates no recorded catch. Data for the period 1983 to 1999 are from Andrew (2001), and have been groomed. Catch estimates for 2000 and 2001 are taken directly from MFish. * includes 133 t caught in Dusky Sound experimental fishery. Catches from SUR 6, 8, and 9 have been pooled because too few permit holders recorded catches in these FMAs to report them singly.

Figure 1: Reported commercial landings and TACC for the nine main SUR stocks. From top: SUR 1A (Northland) and SUR 1B (Hauraki Gulf, Bay of Plenty). 2A (East Coast), SUR 2B (Wairarapa, Wellington). [Continued on next page]. Note that these figures do not show data prior to entry into the QMS.

Figure 1 [Continued]: Reported commercial landings and TACC for the nine main SUR stocks. From top: SUR 3 (South East Coast), SUR 4 (South East Chatham Rise), SUR 5 (Southland), and SUR 7A (Challenger Nelson Marlborough). Note that these figures do not show data prior to entry into the QMS.

Figure 1 [Continued]: Reported commercial landings and TACC for the nine main SUR stocks. SUR 7B (Challenger Westland). Note that these figures do not show data prior to entry into the QMS.

1.2 Recreational fisheries

Recreational catch was estimated using telephone-diary surveys in 1993–4, 1996 (Fisher & Bradford 1998, Bradford 1998) and 2000 (Boyd & Reilly 2002, Boyd et al 2004) (Table 4). There are no estimates of recreational catch from the Chatham Islands. In many instances, insufficient kina were caught to provide reliable estimates of the error associated with the estimates of total harvest. The harvest estimates provided by these telephone-diary surveys are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. In response to these problems and the cost and scale challenges associated with onsite methods, a National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Harvest estimates for kina (in numbers) are given in Table 4 (from Wynne-Jones et al. 2014, no estimates of mean weight were available from boat ramp surveys, Hartill & Davey 2015).

1.3 Customary non-commercial fisheries

There is an important customary non-commercial harvest of kina by Maori for food. Where data are available, only small catches of kina have been reported under the customary non-commercial harvest provisions of the Fisheries Act 1996. In SUR 3, 5, and 7, all catches were less than 1 t per year (Table 5). These catch estimates are probably under-estimates as an unknown proportion of the kina harvested by Maori is caught outside of Taiapure or Mataitai and not recorded as customary non-commercial harvest (P. Grimshaw, Ngai Tahu Development Corporation, pers. comm.). No data are available for other regions of New Zealand (S. Kerins, Te Ohu Kai Moana, pers. comm.).

For the early telephone-diary surveys, catches in numbers were converted to catch in tonnes by assuming an average whole weight of 248.3 g per kina based on equal proportions across a size range 60–110 mm TD and a test diameter-weight relationship ($W = (6.27 \times 10^{-4})TD^{2.88}$) from Dusky Sound (unpublished data). These estimates of catch in tonnes should be considered as indicative only and may be very inaccurate. No estimates of mean weight were available to convert catches in numbers from the national panel survey to catch in tonnes.

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

KINA (SUR)

Table 4: Estimates of recreational harvest of kina using telephone-diary surveys (1993–94, 1996, and 2000 surveys) and the national panel survey (2011–12).

Area	Number (thousands)	CV	Catch (t)*
1993–94 (telephone-diary)

Table 5: Reported customary catch by FMA for SUR 3, 5, and 7.

Year	SUR	Count	Weight (kg)
1998–99	3	100	25
	5	1 522	433
	7	0	0
1999–2000	3	0	0
	5	1 631	405
	7	0	0

Data as numbers caught supplied by Ngai Tahu Development Corporation. Catch in kilograms was estimated using the conversion rules described in the paragraph above.

1.4 Illegal catch

Current levels of illegal harvest are not known.

1.5 Other sources of mortality

Although there is no minimum legal size for kina, some incidental mortality is likely because roe quality (recovery rate and colour) is commonly assessed by opening ‘test’ kina underwater. These animals are not subsequently landed. There are no estimates of the magnitude to this incidental mortality.

2. BIOLOGY

The biology and ecology of kina has been extensively studied; this literature has most recently been reviewed by Barker (2001). *Evechinus chloroticus* is found throughout New Zealand and the sub-Antarctic Islands. Kina has an annual reproductive cycle which culminates in spawning between November and March (Dix 1970, Walker 1984, McShane et al 1994a, 1996, Lamare & Stewart 1998, Lamare 1998). Size at maturity appears to vary considerably and may be as small as 30 mm and as large as 75 mm TD (Dix 1970, Barker et al 1998). In Dusky Sound, kina are reproductively mature at 50–60 mm T.D. (McShane et al 1996). Within these seemingly consistent patterns in the seasonality of the reproductive cycle there are many differences in the gonad size at small spatial scales.

Settlement is likely to be vary between years and appears to differ among locations and habitats (Dix 1972, Walker 1984). Laboratory work has shown that kina larval mortality increased with increasing concentrations of suspended sediment at realistic concentrations (Phillips & Shima 2006). In the field, but not in the laboratory, development abnormalities were found associated with suspended sediment concentrations, this suggests the importance of other environmental factors associated with terrestrial runoff (Schwarz et al 2006). Juvenile settlement and mortality has also been observed to increase with sediment at realistic concentrations in a size-specific manner in the laboratory; this agrees with juvenile patterns of distribution observed in the field (Walker 2007). Few small kina were observed in any of the surveys in Dusky Sound (McShane et al 1993). These results suggest that the productivity of stocks in Fiordland may be low and that recruitment over-fishing is a real possibility.

There is relatively little information available on the interactions between kina and its predators and competitors. Although a wide range of fish and invertebrates eat kina, there is limited evidence that these species control or limit populations of kina in Fiordland. Work in a marine reserve, where large predators such as reef fishes and crayfish are abundant, indicates that predators can control numbers of kina surviving the transition from crevice-bound to open substratum grazing (Cole & Keuskamp 1998, Babcock et al 1999). Babcock et al (1999) have drawn a direct link between the increases in snapper and crayfish populations and the long-term decline in kina populations in the Leigh Marine Reserve. There is however, no evidence that high kina densities limit rock lobster populations (Andrew & MacDiarmid 1991). It is likely, however, that changes in the abundance of kina, and the consequent changes in habitat representation, are part of a complex set of interacting processes, including but not exclusively, increased predation.

Kina compete with a range of invertebrate herbivores, including paua. There is no published evidence that high densities of kina limit paua populations in Fiordland. McShane (1997) reported that paua are abundant in Dusky Sound, and in Chalky and Preservation Inlets, but are rare in the fjords.

Lamare & Mladenov (2000) estimate that kina grow 8–10 mm in their first year of life. Growth rates will vary considerably depending on local conditions but kina may take 8–9 years to reach 100 mm TD, and very large individuals may reach ages of more than 20 years (Lamare & Mladenov 2000).

3. STOCKS AND AREAS

There appear to be few genetic differences in kina populations from Leigh (North Auckland) and Stewart Island (Mladenov et al 1997) which suggests that there is at least some mixing among populations. There is no direct evidence that populations of kina at the Chatham Islands differ genetically from those on the mainland, nor is there evidence that “populations” of kina at the Chatham Islands are dependent on the dispersal of larvae from the mainland.

4. STOCK ASSESSMENT

Although there is a wealth of information on the biology and ecology of this species (see Barker 2001 for reviews), there is relatively little that can be used to assess the status of exploited stocks. There have been no assessments of sustainable yield nor are there estimates of biomass or trends in relative abundance for any Fishstock (Annala 1995).

4.1 Estimates of fishery parameters and abundance

Andrew (2001) reported catch rates from both dive and dredge fisheries but advised caution in the interpretation of catch rate information of sedentary invertebrates, like kina, gathered at broad spatial scales.

Indices of relative abundance using timed swims have been reported for Ariel Reef in SUR 2 (Anderson & Stewart 1993), Chatham Islands (Schiel et al 1995, Naylor & Andrew 2002), and D’Urville Island and Arapawa Island in SUR 7 (McShane et al 1994a). Numerous surveys of kina have been done over the last 30 years in fished areas, mostly by university-based researchers (e.g. Dix 1970, Choat & Schiel

1982, Schiel et al 1995, Cole & Keuskamp 1998, Babcock et al 1999, Wing et al 2001). Naylor & Andrew (2002) reported a range of densities for kina around Chatham Island from 0.17/m² (northwest Chatham Island) to 1.6/m² (south east Chatham Island). These were generally lower than estimates made in the mid 1990s by Schiel et al (1995) (0.2/m² to 6/m²). By contrast, even lower kina densities of around 0.1/m² were reported by McShane et al (1994a) for both Arapawa and D'Urville Island. Dix (1970) reported much higher mean relatively high densities of kina ranging from 2.2/m² in Queen Charlotte Sound to 6/m² at Kaikoura.

4.2 Biomass estimates

McShane & Naylor (1993) reported biomass estimates of 2500 and 500 t respectively for D'Urville and Arapawa Islands (SUR 7), presumably based on an expansion of density estimates reported in McShane et al (1994a) by an area estimate, however, the methods are not detailed.

Biomass was estimated for Dusky Sound and Chalky Inlet (SUR 5) prior to Dusky Sound being opened as an experimental fishery in May 1993 (McShane & Naylor 1991, 1993). Productivity and biomass was to be estimated by depletion methods but this was unsuccessful because only 133 t of the projected 1000 t was caught (McShane et al 1994b) and this catch was insufficient to cause a measurable change in the estimated biomass of kina.

4.3 Yield estimates and projections

MCY has not been estimated for any SUR fishstock. Within SUR 5, an MCY estimate of sustainable yield within Dusky Sound and Chalky Inlet was reported in Annala (1995). This estimate used Method 1 of Annala (1995) for new fisheries based on surveys done by McShane & Naylor (1991, 1993) and an estimate of a reference fishing mortality derived from McShane et al (1994a). The estimated annual sustainable yield of 275 t for these two areas has never been harvested because they are closed to commercial fishing except under special permit.

CAY has not been estimated for any SUR fishstock.

5. STATUS OF THE STOCKS

For all Fishstocks it is not known if current catch levels or TACCs are sustainable, or if they are at levels which will allow the stocks to move towards a size that will support sustainable yields.

KING CRAB (KIC)

(Lithodes aotearoa, Neolithodes brodiei)*Lithodes aotearoa**Neolithodes brodiei*

1. FISHERY SUMMARY

1.1 Commercial fisheries

King crabs (*Lithodes aotearoa* and *Neolithodes brodiei*) were introduced into the Quota Management System on 1 April 2004 with a combined TAC of 90 t and TACC of 90 t (Table 1). There are no allowances for customary, recreational or other sources of mortality. The fishing year is from 1 April to 31 March and commercial catches are measured in greenweight. The two crabs are relatively distinct, and are found at different depths, but may be confused with other species of *Lithodes*.

Landings have been reported from all QMAs, however these landings are small and are unlikely to reflect the real catch as these crabs are generally discarded at sea and remain unreported. Most of the landed catch has been reported under the aggregated code KIC, although there are a few records by species (i.e., *L. aotearoa* [LMU] and *N. brodiei* [NEB]).

Most of the reported landings have come from KIC 2 from 2011–12 to 2015–16, which was fished under a special permit during that time. A special permit was also issued for KIC 6 in the 1996–97 fishing year (Table 1). Target fishing is by potting, although the crabs are taken as bycatch in the orange roughy fishery off the Wairarapa coast and in Queen Scallop dredging off the Otago coast. Figure 1 shows the historical landings and TACC for KIC 4.

1.2 Recreational fisheries

There are no records of recreational use of these crabs, and because of their depth range recreational catch is unlikely.

KING CRAB (KIC)

Figure 1: Reported commercial landings and TACC for KIC 2 (East coast North Island). Note that this figure does not show data prior to entry into the QMS.

1.3 Customary non-commercial fisheries

There are no known records of customary use of these crabs, and because of their depth range customary take is unlikely.

1.4 Illegal catch

There is no known illegal catch of these crabs.

1.5 Other sources of mortality

There is no quantitative information on other sources of mortality, although the crabs are sometimes taken as a bycatch in orange roughy fishing and queen scallop fishing.

*In 1995–96 and 1998–99, 47 kg and 1 kg of LMU were landed respectively, but no FMA was assigned to the landings. In 1996–97 24 kg of NEB was landed but no FMA was assigned to this landing. These reported landings by species are included in the total landings for KIC in those years.

2. BIOLOGY

King crabs belong to the infra order Anomura, and differ from true crabs (Brachyura) in that the last pair of walking legs is reduced and folded inside the carapace.

L. aotearoa is a large, pear-shaped, dark purplish-red or brick red crab that has been found at depths between 120 m and 700 m. from the east coast of Northland to southern parts of the Campbell Plateau. It is a circumpolar, Southern Ocean species growing so large that the distance between the tips of the second legs can reach 1.25 m. The carapace width in males of this species may exceed 200 mm. Females are smaller.

KING CRAB (KIC)

N. brodiei is also pear-shaped, and typically a uniform brick to bright red colour. It is widely distributed from the Three Kings Islands to the Campbell Plateau, where it occurs on soft and rocky bottom between about 800 and 1100 m. Carapace width in this species is up to about 180 mm.

King crabs are thought to aggregate for protection during breeding and moulting. Migrations between shallow and deep waters also probably occur in response to moulting and mating, at least in near-shore populations. They occur mainly on soft substrates but have also been found on rocky bottoms. They are probably omnivorous, although animal food (sessile, sedentary, and mobile invertebrates, and small fish), including dead material, is their predominant food. Their principal predators are fish and seals.

Sexes are separate in all species of king crabs and they appear to be seasonal spawners, probably spawning in summer or autumn.

3. STOCKS AND AREAS

For management purposes stock boundaries are based on FMAs, however, there is currently no biological or fishery information which could be used to identify stock boundaries.

4. STOCK ASSESSMENT

4.1 Estimates of fishery parameters and abundance

There are no estimates of fishery parameters or abundance for any king crab fishstock.

4.2 Biomass estimates

There are no biomass estimates for any king crab fishstock.

4.3 Yield estimates and projections

There are no estimates of *MCY* and *CAY* for any king crab fishstock.

5. STATUS OF THE STOCKS

There are no estimates of reference or current biomass for any king crab fishstock.

KINGFISH (KIN)*(Seriola lalandi)*

Haku

**1. FISHERY SUMMARY**

Kingfish were introduced into the QMS on 1 October 2003, with allowances, TACCs and TACs in Table 1 except that the TACC for KIN 8 was increased from 36 to 45 t in October 2012.

Table 1: Recreational and customary non-commercial allowances, TACCs and TACs by Fishstock.

Fishstock	Recreational Allowance	Customary non-commercial Allowance	Other sources of fishing related mortality	TACC	TAC
KIN 1	459	76	47	91	673
KIN 2	65	18	24	63	170
KIN 3	1	1	0	1	3
KIN 4	1	1	0	1	3
KIN 7	10	2	2	15	21
KIN 8	31	9	7	45	92
KIN 10	1	0	0	1	2

An increased minimum legal size (MLS) to 75 cm (from 65 cm) for recreationally caught kingfish was introduced on 15 January 2004. Kingfish were added to the 6th Schedule of the Fisheries Act (1996) in October 2005 for all fishing methods except setnet and in all areas. A special reporting code for 6th Schedule releases was introduced on 1 October 2006 to allow monitoring of releases. Kingfish released in accordance with 6th Schedule conditions and reported against this code are not counted against ACE. The commercial MLS for kingfish is 65 cm.

KINGFISH (KIN)

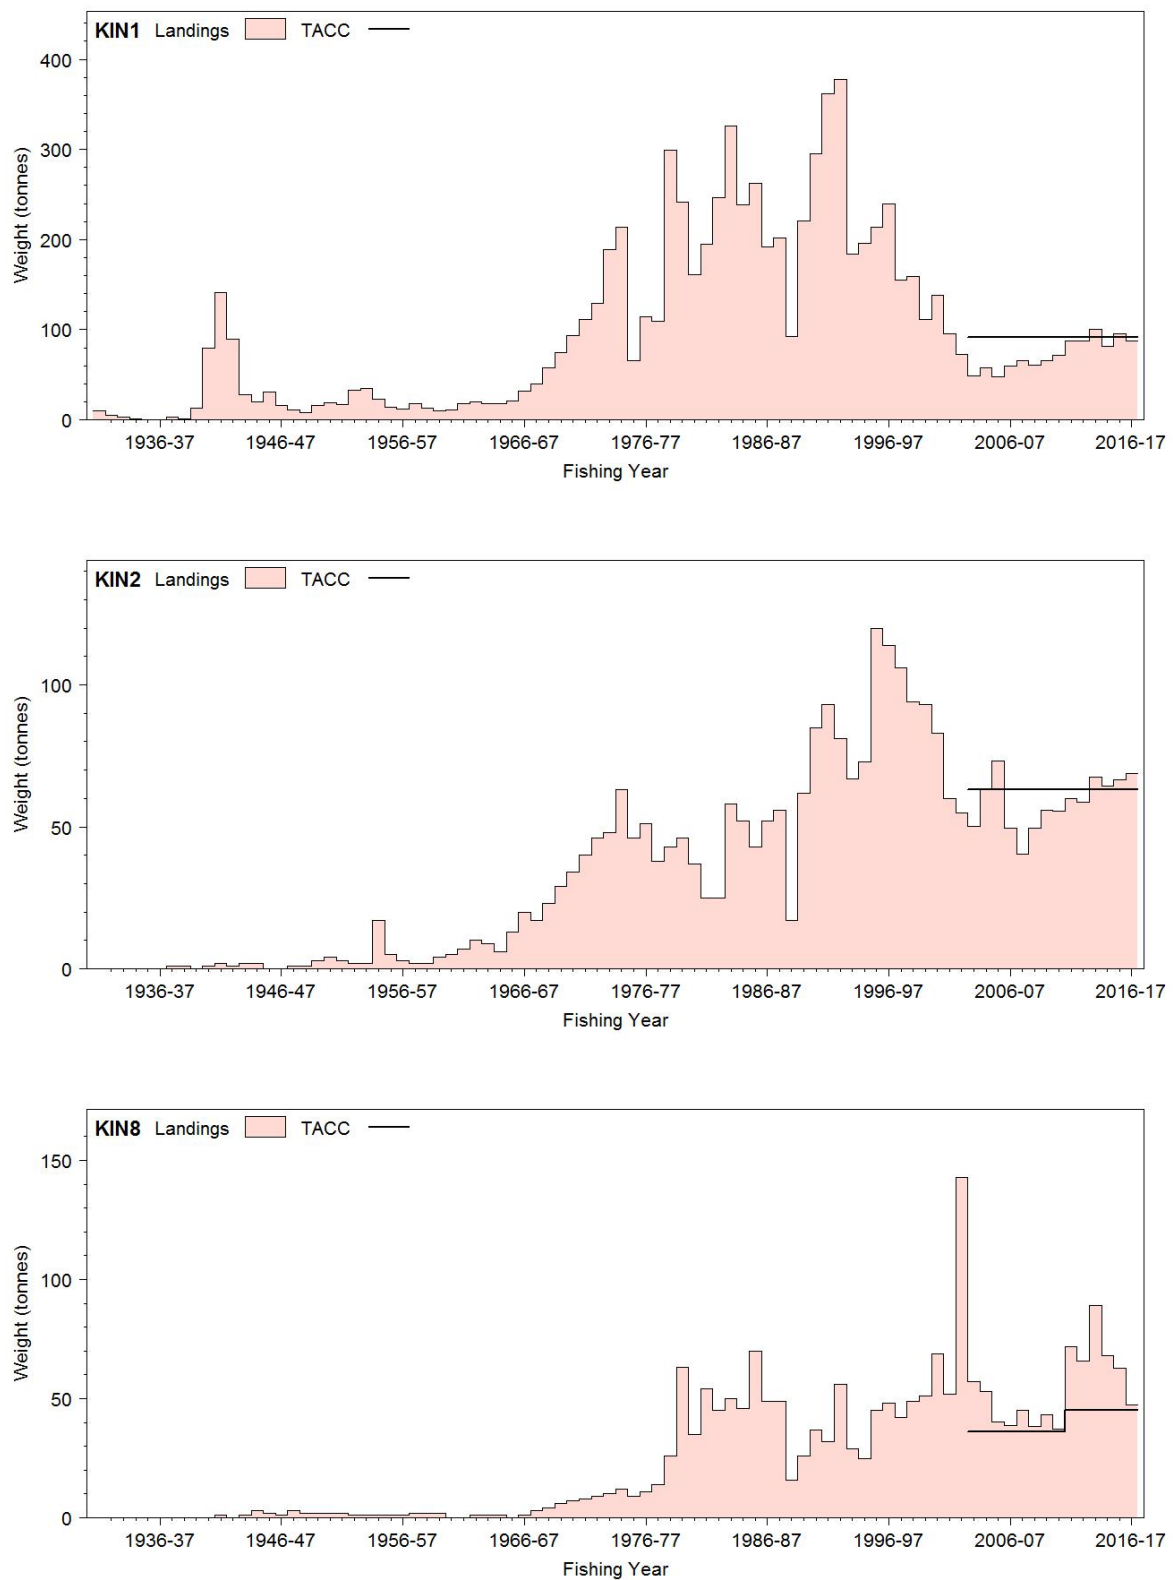

Figure 1: Reported commercial landings and TACC for the three largest KIN stocks. From top to bottom: KIN 1 (Auckland East), KIN 2 (Central East) and KIN 8 (Central Egmont).

1.1 Commercial fisheries

Kingfish commercial landings are reported largely as bycatch of inshore setnet, trawl and longline fisheries. From 1991 to late 2003, targeting of kingfish (as a non-QMS species) was prohibited unless the species was identified on a fisher's permit. A few permit holders were authorized to target kingfish and most of their catch was taken using setnets.

Commercially, kingfish is a moderately high value species and is usually sold as fillets or whole chilled. The main fishing areas for kingfish are the east (KIN 1 and KIN 2) and west coast (KIN 8) of the North Island of New Zealand (Table 2). The largest commercial catches generally come from KIN 1. Landings were relatively large in 1983–84, especially in KIN 1, and were probably due to the greater number of vessels in the fishery prior to the introduction of the QMS in 1986. In addition, there was increased effort and better reporting as fishers sought to establish a catch history for the main species in anticipation of the introduction of the QMS. By 1988–89, reported catches of kingfish had reduced to their lowest levels across most areas. This was most likely due to the under-reporting of less common species in the catch (which includes kingfish) and the introduction of non-QMS restrictions. An increase in kingfish landings in FMA 1 between 1988–89 and 1992–93 and in FMA 2 between 1988–89 and 1991–92 may be due to a number of factors. These include: better reporting of catches; changes in fishing patterns with increased catch by setnet; increased numbers of vessels reporting kingfish catch; and increased targeting of kingfish.

Historical estimated and recent reported kingfish landings and TACCs are shown in Tables 2 and 3, while Figure 1 shows the historical and recent landings and TACC values for the main kingfish stocks.

The total reported catch across all FMAs peaked in 1992–93 at 532 t, with 73% of the catch from KIN 1. By 1993–94, the reported catch of kingfish over all QMAs decreased considerably, mainly because of the reduced catch from KIN 1. Possible reasons for this decrease include: the effect of the October 1993 introduction of a MLS of 65 cm on all methods other than trawl; changes in fishing patterns in the snapper and trevally target setnet, trawl, and bottom longline fisheries (that were responsible for most of the non-target catch of kingfish); decreased target fishing for kingfish; and setnet area closures in FMA 1 from October 1993. The trawl exemption with respect to MLS was removed in December 2000.

The annual catch of kingfish from KIN 1 fluctuated between 100 and 250 t from 1993–94 through to 2000–01 and has remained below 100 t since 2001–02. The kingfish annual catch from KIN 2 declined from the high of 120 t in 1995–96 to 50 t in 2003–04, and has mostly been below 60 t since then. Landings from KIN 8 have averaged approximately 35 t for the last 19 years, with catches ranging from 19–70 t. In 2002–03 landings nearly triple the 2001–02 level were reported in KIN 8, the highest ever landing in this area. Landings returned to near average in 2003–04 and 2004–05, but were still above the TACC. Annual catches in KIN 8 have remained below 50 t since 2005–06, but were often above the 36 t TACC. Although the TACC was increased to 45 t in October 2011 to accommodate previous levels of by-catch, the 2011–12 commercial catch increased substantially to 92 t. In addition to annual catches reported for kingfish QMAs, about 5 t of kingfish has been taken by New Zealand flagged vessels fishing outside NZ fishing waters.

Assuming that kingfish targeting effectively ceased during the mid 1990s, catches since the early 2000s possibly reflect 'true' bycatch levels.

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns: Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings.

Table 3: Reported landings (t) of kingfish by area (QMA) from 1983–84 to 2016–17. From 1986–87 to 2000–01, total landings are from LFRRs and landings by QMA are from CLRs prorated to the LFRR total. Totals include landings not attributed to the listed QMAs. MHR data from 2001–present. [Continued on next page].

* FSU data (Area unknown data prorated in proportion to recorded catch).

§ Some data included in FMA 1.

1.2 Recreational fisheries

Kingfish is highly regarded by recreational fishers in New Zealand for its sporting attributes and large size. Kingfish are most often caught by recreational fishers from private boats and from charter boats, but are also a prized catch for spearfishers and shore based game fishers. Kingfish are recognised internationally as a sport fish, and kingfish caught in New Zealand waters hold 21 of the 22 International Gamefish Association World Records.

1.2.1 Management controls

The main methods used to manage recreational harvests of kingfish are minimum legal size limits (MLS), method restrictions and daily bag limits. Fishers can take up to three kingfish as part their daily bag limit and the MLS is 75 cm.

Recreational fishers have voiced concerns over the reduced availability of large kingfish in some areas. Many clubs, competitions and charter boats have consequently implemented a voluntary one kingfish per person per day limit in response. A number of gamefish clubs have also adopted a minimum size limit of 100 cm for kingfish.

1.2.2 Tag and release

A voluntary recreational tagging programme has released 21 932 kingfish in New Zealand (1975 to 2015). Anglers feel they are contributing to research and conservation of stocks, while still getting recognition of their catch. The research objectives are to collect detailed information on released fish to help characterise the fishery and collect growth and movement information from recaptured fish. There have been 1495 tagged kingfish recaptured in New Zealand (1977 to 2015), with an average of 43 recaptures (and 787 releases) per year over the last 10 years (Table 4).

KINGFISH (KIN)

Table 4: The number of kingfish tagged and recaptured by year for the last 10 years.

	2005–06	2006–07	2007–08	2008–09	2009–10	2010–11	2011–12	2012–13	2013–14	2014–15
Releases	1 016	977	1 120	661	1 381	1 123	613	761	649	722
Recaptures	53	38	55	43	46	54	44	38	31	30

Figure 2: Kingfish straight line distance from release location by days at liberty 1977 to 2013.

Most kingfish are caught close to their release location even after many years. Ninety four percent of recaptures for fish at liberty for 30 days or more were within 100 nautical miles of the release point (Figure 2). The proportion of recaptured kingfish at distances (over 100 miles) increases after 3 years. Kingfish are also capable of extensive movements with three trans-Tasman recaptures recorded.

1.2.3 Estimates of recreational harvest

Recreational catch estimates are given in Table 5. There are two broad approaches to estimating recreational fisheries harvest: the use of onsite or access point methods where fishers are surveyed or counted at the point of fishing or access to their fishing activity; and, offsite methods where some form of post-event interview and/or diary are used to collect data from fishers.

The first estimates of recreational harvest for kingfish were calculated using an offsite approach, the offsite regional telephone and diary survey approach. Estimates for 1996 came from a national telephone and diary survey (Bradford 1998). Another national telephone and diary survey was carried out in 2000 (Boyd & Reilly 2005) and a rolling replacement of diarists in 2001 (Boyd & Reilly 2004) allowed estimates for a further year (population scaling ratios and mean weights were not re-estimated in 2001).

The harvest estimates provided by these telephone diary surveys are no longer considered reliable for various reasons. With the early telephone/diary method, fishers were recruited to fill in diaries by way of a telephone survey that also estimates the proportion of the population that is eligible (likely to fish). A “soft refusal” bias in the eligibility proportion arises if interviewees who do not wish to co-operate falsely state that they never fish. The proportion of eligible fishers in the population (and, hence, the harvest) is thereby under-estimated. Pilot studies for the 2000 telephone/diary survey suggested that this effect could occur when recreational fishing was established as the subject of the interview at the outset. Another equally serious cause of bias in telephone/diary surveys was that diarists who did not immediately record their day’s catch after a trip sometimes overstated their catch or the number of trips made. There is some indirect evidence that this may have occurred in all the telephone/diary surveys (Wright et al 2004).

The recreational harvest estimates provided by the 2000 and 2001 telephone diary surveys are thought to be implausibly high for many species, which led to the development of an alternative maximum count aerial-access onsite method that provides a more direct means of estimating recreational harvests for suitable fisheries. The maximum count aerial-access approach combines data collected concurrently from two sources: a creel survey of recreational fishers returning to a subsample of boat ramps throughout the day; and an aerial survey count of vessels observed to be fishing at the approximate time of peak fishing effort on the same day. The ratio of the aerial count in a particular area to the number of interviewed parties who claimed to have fished in that area at the time of the overflight was used to scale up harvests observed at surveyed ramps, to estimate harvest taken by all fishers returning to all ramps. The methodology is further described by Hartill et al (2007).

This aerial-access method was first employed and optimised to estimate snapper harvests in the Hauraki Gulf in 2003–04. It was then extended to survey the wider SNA 1 fishery in 2004–05 and to provide estimates for other species, including kingfish. The PELWG indicated that the kingfish estimate should be considered with considerable caution due to the limited overlap between this methods sampling technique and the fisheries for kingfish, e.g., the target fisheries for kingfish are usually in offshore areas from launches which were not sampled by the boat ramp survey. For this reason the results from this survey have not been accepted or included in the working group report at this time.

Table 5: Recreational harvest estimates for kingfish stocks. The telephone/diary surveys ran from December to November but are denoted by the January calendar year. The national panel survey ran through the October to September fishing year but is denoted by the January calendar year. Mean fish weights were obtained from boat ramp surveys (for the telephone/diary and panel survey harvest estimates). (Source: Tierney et al 1997, Bradford 1997, Bradford 1998, Boyd & Reilly 2002, Boyd et al. 2004, Wynne-Jones et al. 2014).

#No harvest estimate available in the survey report, estimate presented is calculated as average fish weight for all years and areas by the number of fish estimated caught.

In response to the cost and scale challenges associated with onsite methods, in particular the difficulties in sampling other than trailer boat fisheries, offsite approaches to estimating recreational fisheries harvest have been revisited. This led to the development and implementation of a national panel survey for the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and catch information collected in standardised phone interviews. Note that the national panel survey estimate does not include recreational harvest taken

KINGFISH (KIN)

under s111 general approvals on commercial vessels. The estimates of harvest from the panel survey were compared with direct estimates (using onsite surveys) for key stocks in FMA 1 (Edwards & Hartill 2015) and are considered reliable.

1.3 Customary non-commercial fisheries

Kingfish is an important traditional food fish for Maori, but no quantitative information on the level of Maori customary non-commercial catch is available. The extent of the traditional fisheries for kingfish in the past is described by the Muriwhenua Fishing Report (Waitangi Tribunal 1988). Because of the coastal distribution of the species and its inclination to strike lures, it is likely that historically Maori caught considerable numbers of kingfish.

1.4 Illegal catch

There is no known illegal catch of kingfish.

1.5 Other sources of mortality

The extent of any other sources of mortality is unknown, however, handling mortality for sub-MLS size fish is likely to occur in both the recreational (sub 75 cm) and commercial (sub 65 cm) fisheries. Recreational fishers also release a large proportion of legal size kingfish.

2. BIOLOGY

In New Zealand, kingfish are predominantly found in the northern half of the North Island but also occur from 29° to 46° S, Kermadec Islands to Foveaux Strait (Francis 1988) and to depths of 200 m. Kingfish are large predatory fish with adults exceeding one and a half metres in length. They usually occur in schools ranging from a few fish to well over a hundred fish. Kingfish tend to occupy a semi-pelagic existence and occur mainly in open coastal waters, preferring areas of high current and or tidal flow adjacent to rocky outcrops, reefs and pinnacles. However, kingfish are not restricted to these habitats and are sometimes caught or observed in open sandy bottom areas and within shallow enclosed bays.

Estimates of age have been derived from opaque-zone counts in sagittal otolith thin sections. Estimates of kingfish von Bertalanffy growth parameters were also derived from recreational tagging data and otoliths collected from the eastern Bay of Plenty. Estimates of K and L_{∞} were similar being 0.128 and 130 cm from the otolith age data and 0.130 and 142 cm from the tagging increment data respectively (Table 6). The hard-structure ageing techniques have yet to be validated for New Zealand kingfish, although the position of the first annulus has been validated using regular samples of 0+ year old fish from a fish aggregating device (Holdsworth et al 2013; Francis et al 2005).

A Bayesian analysis of length and maturity data suggests that the length of 50% maturity is 97 cm in females and 83 cm in males.

Estimates of M ranged from 0.20–0.25, however, these estimates are thought to represent an upper bound as the samples were taken from an exploited population.

Available biological parameters relevant to stock assessment are shown in Table 6.

3. STOCKS AND AREAS

A study based on meristic characters and parasite loads suggests two stocks of kingfish off the west and east coasts. These stocks are contained within the Tasman current on the west coast and the east Auckland current and east Cape current on the east coast, with little mixing between them. The east coast stock may be further subdivided into northeast and Hawkes Bay stocks based on limited exchange from tagging studies and parasite marker prevalence.

Tagging results suggest that most adult kingfish do not move outside local areas, with many tag returns close to the release site (Figure 2). However, some tagged kingfish have been found to move very long distances; there are validated reports of New Zealand tagged kingfish being caught in Australian waters and Australian tagged kingfish being recaptured in New Zealand waters.

4. STOCK ASSESSMENT

4.1 KIN 1 catch at age sampling

The age composition of the KIN 1 target recreational charter boat fleet catch was sampled in 2010–11 and in 2014–15 for the purpose of estimating total mortality (Z). Sampling was stratified into two regions East Northland and Bay of Plenty, and two strata based on distance from the shore: inshore on the North Island continental shelf (<200m) and around four offshore islands and pinnacles. Representative samples of kingfish over the MLS were obtained from the offshore Bay of Plenty and inshore east Northland with 831 and 863 kingfish measured over 75 cm in these two strata in 2014–15 (Table 7). Sampling was less successful in the inshore Bay of Plenty and the offshore east Northland but deemed usable by the NINSWG.

All kingfish were measured and recorded per trip on participating vessels. Age length keys were developed using otoliths from retained fish. Bay of Plenty offshore samples in 2010–11 included more old fish than those from inshore (Holdsworth et al 2013). The Bay of Plenty offshore age distribution in 2014–15 (Figure 3) was similar to that observed from the Bay of Plenty in 2010–11, although more older fish were evident in the 2014–15 sample. In 2014–15 there was a mode at age 5 in East Northland and age 6 in Bay of Plenty (Figure 3).

Table 7: Number of kingfish lengths and otolith sets collected in 2014–15 from the recreational fishery.

	KIN measured >75	Otoliths collected	Otoliths used in the age-length-key
Inshore Bay of Plenty	211	57	212
Offshore Bay of Plenty	831	156	
Inshore EN/HGU	863	217	271
Offshore East Northland	318	55	

Figure 3: Kingfish age composition by region for inshore and offshore samples in 2014–15.

4.2 Estimates of fishery parameters and abundance

The Working Group agreed there was no valid method for combining inshore and offshore age frequencies by region for the purpose of estimating regional total mortality (Z), recommending instead that total mortality estimates be derived solely from the offshore age frequencies.

Total mortality estimates for offshore areas ranged from 0.19 to 0.25 for 2014–15 (Table 8). The $F_{SB40\%}$ target reference point for kingfish is 0.1, as derived by SSB/R methods (Holdsworth et al 2013). Assuming an instantaneous natural mortality rate (M) of 0.2; the target total mortality (Z) rate for kingfish is 0.3. None of the 2014–15 derived Z estimates given in Table 8 are higher than 0.3, suggesting that overfishing of kingfish in offshore areas of the Bay of Plenty and East Northland was unlikely. Although movement has been recorded between inshore and offshore areas, the relationship between these areas is unknown.

Table 8: Total mortality (Z) estimates for KIN 1 sub-regions as derived from catch-curve analysis (Chapman & Robson) of recreational charter-boat catch-at-age data by fishing year, assuming 6 years is the age at full recruitment. The offshore estimate for the Bay of Plenty in 2009–10 was for the White Island area only and the offshore estimate for Northland in 2014–15 was for the Three Kings Area only. Bootstrap CVs are shown in parentheses.

Sub-Region	EN/HG		BoP	
	2009–10	2014–15	2009–10	2014–15
Inshore	0.87 (0.12)	0.49 (0.08)	0.50 (0.14)	0.29 (0.09)
Offshore	–	0.19 (0.08)	0.30 (0.14)	0.25 (0.07)

4.3 Biomass estimates

Few kingfish are encountered in trawl surveys because they are capable of swimming faster the nets, suggesting that trawling is not a suitable method for monitoring changes in kingfish abundance. Kingfish are amenable to mark-recapture studies. However, up to now, tagging studies have been conducted solely to describe kingfish movement patterns and to estimate growth. Data from these programmes are inadequate to estimate stock biomass because tag releases and recoveries are voluntary, not systematic.

4.4 Yield estimates and projections

No information is available.

4.5 Other factors

Kingfish in New Zealand can be regarded as a high value species from customary, commercial and recreational perspectives. Catch records from fishing clubs and amateur charter vessels show the number and size of kingfish has increased in recent years.

4.6 Future research needs

- Sensitivity analyses to determine the effect of progressively increasing the age of full recruitment on the estimates should be conducted.
- Selectivity appears to differ considerably by method (bait, jig) and area. A separate analysis should be undertaken for the bait fisheries only.
- Improved data to better understand inshore – offshore movements should be collected.
- CPUE based on charter boat catch and effort forms should be improved by reporting released kingfish less than the MLS separately from larger released kingfish.

5. STATUS OF THE STOCKS

Stock Structure Assumptions

The movement of New Zealand kingfish has been extensively investigated through mark-recapture programmes. Although some kingfish moved considerable distances (e.g. from New Zealand to Australia) most kingfish were recaptured close to the site of release, regardless of time at liberty. It is therefore assumed that New Zealand kingfish are comprised of several biological stocks. In addition to the results from tagging studies, the age structure of recreational catches suggests that kingfish off East Northland and in the Bay of Plenty in KIN 1 comprise separate stocks.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Unknown
Recent Trend in Fishing Intensity or Proxy	Since previous estimates were made in 2010, <i>F</i> appears to have declined for Inshore BPLE and Offshore BPLE (although White Island was the only BPLE area assessed in 2010); likely to have been low for the last decade in all BPLE areas
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-
Projections and Prognosis	
Stock Projections or Prognosis	Catch curve analysis from recent catch sampling (2014–15) indicates that total mortality is low for both the inshore and offshore regions, with fishing mortality below natural mortality and close to the target. Given the low TACC for KIN 1, inclusion on Schedule 6, increased MLS, and practice of catch and release by recreational anglers, stock size is unlikely to decline in the medium-term.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown for both inshore and offshore areas Hard Limit: Unknown for both inshore and offshore areas
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unlikely (< 40%) for both inshore and offshore areas

Assessment Methodology and Evaluation

Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Estimates of total mortality using Chapman-Robson estimator	
Assessment dates	Latest assessment: 2016	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Age structure of recreational catch in 2014–15 - Instantaneous rate of natural mortality (<i>M</i>) of 0.20 based on a maximum age of 23 years. - Age at 50% maturity (6 yr) - Age at MLS (4 yr) - Growth rate 	1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Uncertainty in the estimate of <i>M</i> - Uncertain relationship between inshore and offshore areas; available data do not support much movement of inshore fish to offshore areas 	

Qualifying Comments

The Z estimates are unweighted by relative catch by method (bait, jig) and area. The selectivity of the two capture methods differs substantially.

Fishery Interactions

Commercial kingfish catch is almost all bycatch in fisheries for other species.

KIN 1 – East Northland/Hauraki Gulf

Stock Status	
Year of Most Recent Assessment	2016
Assessment Runs Presented	Total mortality estimates from catch curve analysis for Inshore ENHG and Offshore ENHG
Reference Points	Target: $F_{SB40\%}$ (current estimate is $F_{SB40\%} = 0.1$) Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{SB40\%}$
Status in relation to Target	Inshore ENHG: F is Unlikely ($< 40\%$) to be at or below the target Offshore ENHG: F is Likely ($> 60\%$) to be at or below the target
Status in relation to Limits	Soft Limit: Unknown Hard Limit: Unknown
Status in relation to Overfishing	Inshore ENHG: Overfishing is Likely ($> 60\%$) to be occurring Offshore ENHG: Overfishing is Unlikely ($< 40\%$) to be occurring

Historical Stock Status Trajectory and Current Status-

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	-
Recent Trend in Fishing Mortality or Proxy	Inshore ENHG: Unknown Offshore ENHG: Unknown; likely to have been low for the last decade

KNOBBED WHELK (KWH)*(Austrofusus glans)***1. FISHERY SUMMARY**

Knobbed whelks (*Austrofusus glans*) were introduced into the Quota Management System on 1 October 2006. The fishing year is from 1 October to 30 September and commercial catches are measured in greenweight. TACs have been allocated in 10 QMAs (Table 1). This species is managed under Schedule 6 of the Fisheries Act for all stocks, which allows for them to be returned to where they were taken (as soon as practicable after being taken) providing they are likely to survive.

Table 1: Current TAC, TACC and allowances for customary fishing, recreational fishing and other sources of mortality for *Austrofusus glans*.

QMA	TAC (t)	TACC (t)	Customary fishing	Recreational fishing	Other sources of mortality
KWH1	3	1	1	1	0
KWH 2	3	1	1	1	0
KWH 3	5	3	1	1	0
KWH 4	8	6	1	1	0
KWH 5	3	1	1	1	0
KWH 6	4	2	1	1	0
KWH 7A	53	50	1	1	1
KWH 7B	3	1	1	1	0
KWH 8	3	1	1	1	0
KWH 9	3	1	1	1	0
Total	88	67	10	10	1

1.1 Commercial fisheries

Target fishing for knobbed whelks is by baited pots. Because economic returns for whelk fishing are poor, most of the historical catch is bycatch from oyster and scallop dredging and from bottom trawling. Due to the low value of this species it is likely that there is a high level of unreported discarded catch.

Landings shown in Table 2 for the period 1990–91 to 2005–06 were recorded under the generic code for whelks (WHE), however the Ministry considers that in FMA 1, 2, 7, and 8, most reported landings were of the knobbed whelk *Austrofusus glans*. In FMA 3, 4, 5, and 6, the Ministry considers that about a third of reported landings were of the knobbed whelk, while the remainder were the large ostrich foot shell *Struthiolaria papulosa*.

Reported landings of knobbed whelk in FMA 1, FMA 2, and FMA 8 have been relatively low and variable since the 1990s and have been (largely or all) accounted for as bycatch. In FMA 7 in the early 1990s

KNOBBED WHELK (KWH)

higher catches were reported as part of experimental fisheries in Golden and Tasman Bay to provide stock assessment information in these areas (Tables 2 and 3). Landings are split into two tables (before and after the 2006 fishing year) as reporting requirements changed when knobbed whelks entered the QMS.

Table 2: Reported landings (t) of whelks (WHE) by FMA from 1990–91 to 2005–06 from landing returns. See section 1.1 for an explanation of the proportion of WHE that are considered to be knobbed whelks.

1.2 Recreational fisheries

There are no estimates of recreational catch.

1.3 Customary non-commercial fisheries

There are no estimates of current customary catch.

1.4 Illegal catch

There is no known illegal catch of this whelk.

1.5 Other sources of mortality

There is no information on other sources of mortality for this whelk.

2. BIOLOGY

The knobbed whelk *A. glans*, is a widely distributed gastropod found from low tide to about 600 m (Powell 1979). This carnivorous whelk grows up to 5 cm long, and occurs throughout New Zealand where it is found on sandy/silt/mud substrate. There is very little published about the biology of this species; most references are identification notes or records of occurrence. It is a scavenger that buries in the substrate when not feeding. A wide variety of invertebrates including polychaetes, gastropods, and bivalves occur within the wide depth range of the knobbed whelk, but no interdependent relationships are documented with *A. glans*.

3. STOCKS AND AREAS

For management purposes stock boundaries are based on FMAs. There is no biological information on stock structure, recruitment patterns, or other biological characteristics which might indicate alternative stock boundaries.

4. STOCK ASSESSMENT

4.1 Estimates of fishery parameters and abundance

There are no estimates of fishery parameters or abundance for any knobbed whelk fishstock.

4.2 Biomass estimates

There are no biomass estimates for any knobbed whelk fishstock.

4.3 Yield estimates and projections

There are no estimates of *MCY* for any knobbed whelk fishstock.

There are no estimates of *CAY* for any knobbed whelk fishstock.

5. STATUS OF THE STOCKS

- **KWH 7A** - *Austrofusus glans*

Stock Status	
Year of Most Recent Assessment	No formal assessment done of any of the stocks
Assessment Runs Presented	-

LEATHERJACKET (LEA)*(Meuschenia scaber)*

Kokiri, Hiriri

**1. FISHERY SUMMARY**

Leatherjacket was introduced into the QMS on 1 October 2003, with allowances, TACCs and TACs shown in Table 1.

Table 1: Recreational and Customary non-commercial allowances, TACCs and TACs for leatherjacket by Fishstock.

Fishstock	Recreational Allowance	Customary Non-Commercial Allowance	Other sources of mortality	TACC	TAC
LEA 1	5	1	9	188	203
LEA 2	2	1	57	1 136	1 196
LEA 3	2	1	5	100	108
LEA 4	1	1	1	7	10
LEA 10	0	0	0	0	0
Total	10	4	72	1 431	1 517

1.1 Commercial fisheries

Nationally, very small landings were first reported in 1948. Most of the current leatherjacket catch is taken as a bycatch, and it is very likely that leatherjacket has always been primarily a bycatch species. From only a few tonnes in the early 1960s, reported landings increased to 200–400 t in the 1970s, 1980s and early 1990s (Table 2). Figure 1 shows the historical landings and TACC values for the main leatherjacket stocks. Landings increased further in the late 1990s to around 1 000 to 1 300 t, but have decreased to less than 600 t since 2010–11. It is possible actual catches were higher than reported prior to the 1970s, but that some catches were discarded without being reported due to low market demand in this period. On average over the last four years total landings have only been 41% of the TACC.

LEATHERJACKET (LEA)

Table 2: Reported landings (t) for the main QMAs from 1931 to 1982.

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns; Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings. Data were aggregated to FMA using methods and assumptions described by Francis & Paul (2013).

Table 3: Reported commercial landings (tonnes) of leatherjacket by fishstock for the fishing years from 1989–90 to 2016–17. Landings for LEA 10 have not been shown as these were negligible and were rounded to zero.

Fishstock FMA (s)	LEA 1 1&9		LEA 2 2&8		LEA 3 3, 5 & 6		LEA 4 4		Total

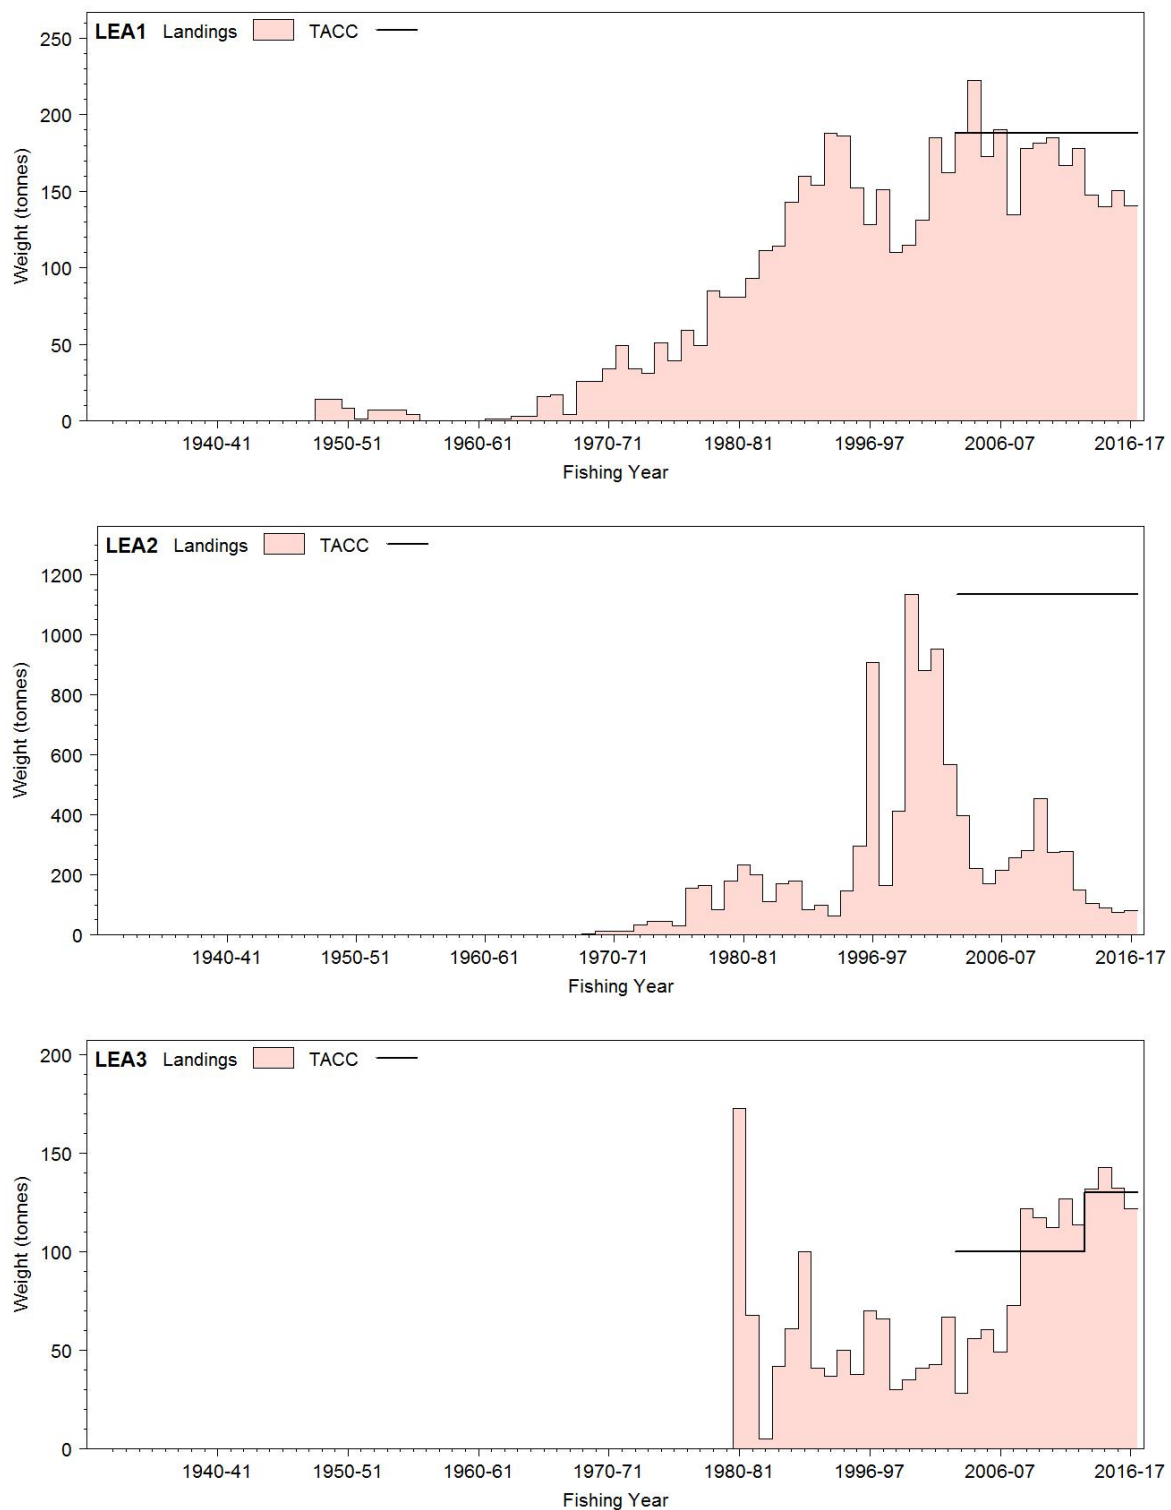

Figure 1: Reported commercial landings and TACCs for the main LEA stocks. From top to bottom: LEA 1 (Auckland), LEA 2 (Central), and LEA 3 (South East).

1.2 Recreational fisheries

Leatherjackets are seldom caught by hook and line but recreational fishers, especially in the northern region, take some leatherjacket by spear fishing, in rock lobster pots and in setnets. No estimates of recreational harvest of leatherjacket were generated from the telephone-diary surveys conducted in 1994, 1996 and 2000 because so few were reported. A National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a

LEATHERJACKET (LEA)

full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Harvest estimates (in numbers of fish) for leatherjacket are given in Table 4 (from Wynne-Jones et al 2014, no estimates of mean weight were available from boat ramp surveys, Hartill & Davey 2015).

Table 4: Recreational harvest estimates (in numbers of fish) for leatherjacket stocks (Wynne-Jones et al 2014).

Stock	Year	Method	Number of fish	Total weight (t)	CV
LEA 1	2011/12	Panel survey	1 599	-	0.68
LEA 2	2011/12	Panel survey	831	-	0.58
LEA 3	2011/12	Panel survey	506	-	0.65
LEA total	2011/12	Panel survey	2 936	-	0.42

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

There is no quantitative information available to allow the estimation of the amount of leatherjacket taken by customary non-commercial fishers.

2. BIOLOGY

The New Zealand leatherjacket (*Meuschenia scaber*) is present around much of New Zealand, but is most common in the north. Trawl survey records show it to be widespread over the inner shelf north of East Cape and Cape Egmont, in the South Taranaki Bight, in Tasman and Golden Bays, Pegasus Bay and the South Canterbury Bight, extending to depths below 100 m, but with greatest abundance at 10–60 m (Anderson et al 1998). It was less commonly caught along the east coast of the North Island south of East Cape, off the northeast South Island (Cook Strait to Pegasus Bay), northwest South Island (Cape Farewell to Cape Foulwind), and around the South Otago and Southland coast. It has not been taken by trawl on the west coast south of Cape Foulwind.

The New Zealand leatherjacket also occurs in Australia, from New South Wales to the southern coast of West Australia. In the Australian southeast trawl fishery, *Meuschenia scaber* is the main leatherjacket species caught (Yearsley et al 1999). It was once believed that two similar species of leatherjacket occurred in New Zealand – ‘rough’ and ‘smooth’ – but these are now considered to be a single species with variable colouring. Kokiri is the Maori name, but is not in common usage. ‘Creamfish’ is a New Zealand trade name for the processed (headed/gutted/skinned) product, rather than a name for the fish itself.

Leatherjacket usually occur near reefs and over rough seafloor, but may be found over sand or some distance above the bottom. Although not a schooling species, it does occur in small groups.

A recent study showed that fifty percent sexual maturity was attained at 19 cm and 1.5 yrs in the Hauraki Gulf, and there were not significant differences between sexes (Visconti et al 2017, 2018). Maximum age was 9.8 yrs for males and 18.1 yrs for females. Males defend territories and eggs are laid within nests on the seafloor from late winter to early summer (Ayling & Cox 1982, Milichich 1986, Visconti et al 2017, 2018).

3. STOCKS AND AREAS

3.1 Biomass estimates

There have been no biological studies directly relevant to the recognition of separate stocks.

Figure 2: Leatherjacket biomass estimates from the west coast South Island inshore trawl survey time series. Error bars are \pm two standard deviations.

The west coast South Island (WCSI) trawl survey probably monitors adult biomass and most of the survey catch comes from Tasman and Golden Bays. The total biomass estimates are shown in Figure 2. Biomass estimates have been relatively stable throughout the time series.

East coast South Island winter trawl survey biomass estimates in the core strata (30–400 m) are not valid given that so few fish were caught, and coefficients of variations are generally high ranging from 36 to 76% (mean = 55%, up to 2012) and no biomass estimates are provided (Figure 3). Most of the biomass is captured in the 10–30 m depth indicating that the core plus shallow strata (10–400 m) is the only valid depth range within which to monitor leatherjacket biomass; although it is doubtful that these surveys index leatherjacket abundance given that they are found more commonly over foul ground and hence not fully available to trawl gear (Beentjes & MacGibbon 2013).

Figure 3: Leatherjacket total biomass for the ECSI winter surveys in core strata (30–400 m), and core plus shallow strata (10–400 m) in 2007, 2012, 2014, and 2016. Error bars are 2 Standard Deviations.

3.2 Length distributions

LEA were not caught in significant numbers on the ECSI winter surveys until 2007 when the shallow strata were included in the surveys. The length distributions in the core plus shallow strata (10–400 m) in 2007 and 2012 show at least three clear modes at about 10 cm, 16 cm, and 23 cm (combined males, females, and unsexed) (Beentjes & MacGibbon 2013). The core plus shallow strata survey is monitoring both pre-recruited cohorts, and fish in the recruited size range.

4. STOCK ASSESSMENT

There has been no scientific assessment of the maximum sustainable yield, reference or current biomass of any of the leatherjacket stocks.

A characterisation and CPUE analysis for the LEA 3 fishery was undertaken by Langley (2013). Leatherjacket in LEA 3 are landed throughout the year, taken almost exclusively by bottom trawl gear in Statistical Areas 021–025 and 030 (Figure 4). Almost all of the LEA catch is taken in the 10–50 m depth range. The characterisation revealed that most of the increase in LEA 3 catch since 2005–06 is attributable to increased landings of leatherjacket catch from bottom trawls targeting spiny dogfish in Foveaux Strait (025).

A CPUE standardisation was undertaken using catch and effort data that included all trips that landed or targeted LEA 3, but did not include trips that did not catch LEA 3. Landed catch was assigned to effort records proportional to estimated catch, following the Starr (2007) methodology, with some refinements where the data were aggregated to CELR equivalent format (vessel/day/method/statistical area/target species) and then the records were defined as CELR equivalent. This method was somewhat problematic due to differences in the reliability of reporting of fishing location and target species between the CELR and TCER form types. The Foveaux Strait and Canterbury Bight fisheries were analysed separately. The Foveaux Strait analysis was rejected by the Working Group and is therefore not reported further.

The Canterbury Bight analysis was limited to the bottom trawl (BT) fishery in Statistical Areas 020 and 022, targeting a range of target species (RCO, BAR, FLA, ELE, TAR, WAR and GUR). The dataset included trips where 1 kg or more of LEA 3 were landed. The analysis had large numbers of very small catches. Eight vessels accounted for 80% of the catch. The working group requested that the Canterbury Bight delta lognormal model targeting FLA, ELE, GUR from 2002 (Target FLA, GUR, ELE post QMS) be used as these are the years when the reporting is likely to be more reliable. There was an indication that CPUE from the Canterbury Bight fishery has increased since the early 2000s, and these indices were robust to some key assumptions. The index (Figure 5) showed that the CPUE remained low at the start of the series and then began to increase from 2007–08 to 2011–12. However, some concerns were raised about the low number of vessels in the analysis and the development of new markets for this species that may have increased targeting or retention of this species in recent years, suggesting that the index may not be reliable as an index of abundance.

The Working Group concluded that this analysis only pertains to the stock unit for the East Coast of the South Island; is the best available information on the stock abundance at this stage but trawl survey data may provide better information in the medium and long-term; and that this is a Level 2 assessment and should be given a medium or mixed (2) overall assessment quality rank

Figure 4: Distribution of reported catch for bottom trawl by Statistical Area in LEA 3 and fishing year from trips which landed leatherjacket in LEA 3 (Langley 2013).

Figure 5: A comparison of three standardised CPUE indices for leatherjacket on the East Coast South Island Langley (2013).

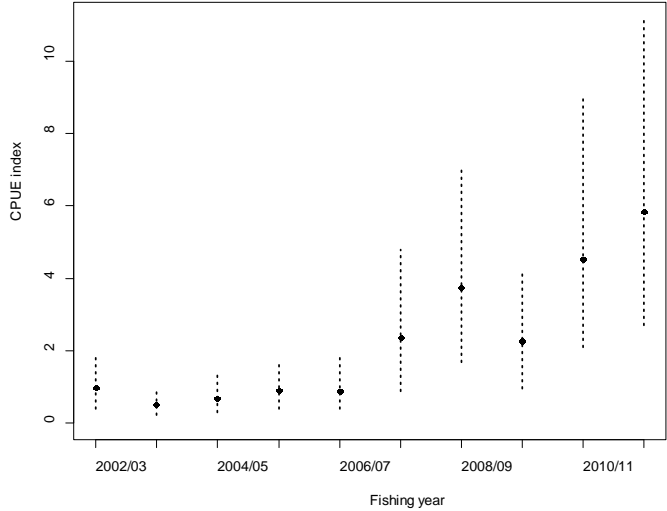

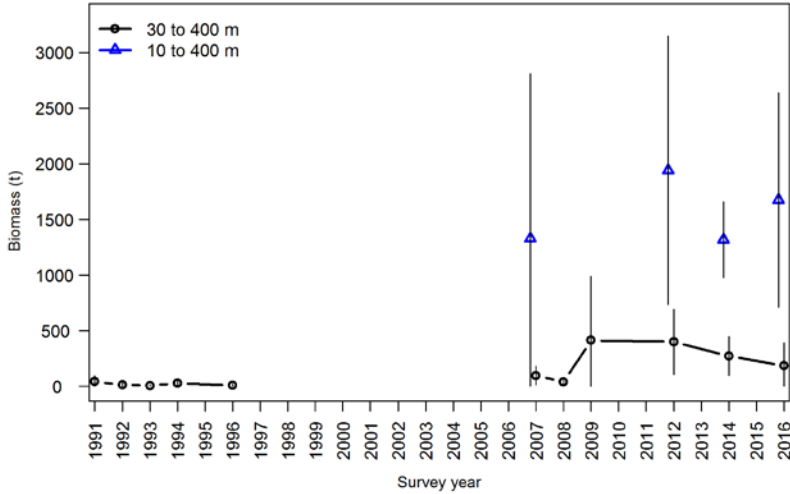

5. STATUS OF THE STOCK

Stock Structure Assumptions

Stock structure is unknown but for management purposes the QMA boundaries are assumed to represent the stock boundaries for this species. There are two distinct areas of catch distribution within LEA 3 (Foveaux Strait and East Coast South Island) and these may represent distinct biological stocks.

LEATHERJACKET (LEA)

- **LEA 3** (East Coast South Island only)

Stock Status	
Year of Most Recent Assessment	2013
Assessment Runs Presented	CPUE: Target FLA, GUR, ELE post QMS
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: F_{MSY}
Status in relation to Target	Unknown
Status in relation to Limits	Soft Limit: Unknown Hard Limit: Unlikely (< 40%)
Status in relation to Overfishing	Unknown
Historical Stock Status Trajectory and Current Status	
	
<p>The 2013 standardised CPUE index for leatherjacket on the East Coast South Island.</p>	
<p style="text-align: center;">LEA</p> 	
<p>Biomass and 95% confidence intervals (total biomass only) for leatherjacket caught by the ECSI trawl survey core strata (30–400), and core plus shallow strata (10–400 m).</p>	

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	CPUE remained low at the start of the series (2002) and then began to increase from 2007–08 to 2011–12. The biomass index from the East Coast South Island trawl survey 30–400 m strata has increased since 2008.

Recent Trend in Fishing Intensity or Proxy	Unknown because new markets for this species may have increased targeting or retention in recent years.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Unknown
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unknown

Assessment Methodology and Evaluation		
Assessment Type	Level 2 - Partial Quantitative Stock Assessment	
Assessment Method	Standardised CPUE	
Assessment Dates	Latest assessment: 2013	Next assessment: Unknown
Overall assessment quality rank	2 - Medium or Mixed Quality: CPUE may be compromised by the low number of vessels in the analysis and trends in targeting or retention of leatherjacket; the trawl survey has only covered the entire habitat since 2007.	
Main data inputs (rank)	- catch and effort data from bottom trawl sets targeting FLA, GUR and ELE - trawl survey biomass index	2 - Medium or Mixed Quality: few vessels in analysis 2 - Medium or Mixed Quality: limited years with full coverage of LEA area
Data not used (rank)	- Foveaux Strait CPUE index - Trawl survey biomass estimates from the 10–400 m strata.	3 – Low Quality: based on only a single vessel that has recently started targeting LEA 3 – Low Quality: confidence intervals large and only two data points
Changes to Model Structure and Assumptions	New model	
Major sources of Uncertainty	The low number of vessels in the analysis and new markets for this species may have increased targeting or retention in recent years. Trends in CPUE may therefore be a result of changes in reporting and retention rather than abundance. Total trawl survey biomass estimates for the entire survey area (10–400 m) have large confidence intervals.	

Qualifying Comments
-

Fishery Interactions
Leatherjacket are landed in fisheries targeting RCO, BAR, FLA, ELE, TAR, WAR and GUR, but are most commonly caught in FLA, GUR and ELE target bottom trawl sets. Some concerns have been raised about catch being taken in “hay paddocks”; these are polychaete worm beds that are biologically sensitive, habitat forming areas, which appear to be diminishing in areal extent as a consequence of disturbance from bottom trawling. Interactions with other species are currently being characterised.

LEATHERJACKET (LEA)

Research Needs

Fishery characterisations that include interviews with fishers and processors are required to assess the degree to which changes in fishing practices and economic drivers may have influenced CPUE trends. Trawl surveys need to continue to include the shallow strata in order to monitor the abundance of leatherjacket on the east coast of the South Island.

Reported landings and TACCs by Fishstock for the 2016–17 fishing year are summarised in Table 5.

Table 5: Summary of TACCs (t) and reported landings (t) of leatherjacket for the most recent fishing year.

LIN 7	1	1	62	3 080	3 144
Total	42	22		23 182	22 493

1.1 Commercial fisheries

Ling was introduced into the Quota Management System (QMS) on 1 October 1986. Ling are widely distributed through the middle depths (200–800 m) of the New Zealand EEZ, particularly south of latitude 40° S. From 1975 to 1980 there was a substantial longline fishery on the Chatham Rise (and to a lesser extent in other areas) carried out by Japanese and Korean longliners. Since 1980 ling have been caught by large trawlers, both domestic and foreign owned, and by small domestic longliners and trawlers. In the early 1990s the domestic fleet was increased by the addition of several larger longliners with autoline equipment, resulting in a large increase in the catches of ling off the east and south of South Island (LIN 3, 4, 5 and 6). However, since about 2000 there has been a declining trend in catches taken by line vessels in most areas, offset, to some extent, by increased trawl landings.

The principal grounds for smaller domestic vessels are the west coast of South Island (WCSI) and the east coast of both main islands south of East Cape. For the large trawlers the main sources of ling are Puysegur Bank and the slope of the Stewart-Snares shelf and waters in the Auckland Islands area, and the Chatham Rise, primarily as bycatch of target fisheries for hoki. Longliners fish mainly in LIN 3, 4, 5 and 6. In 2016–17, landings from Fishstocks LIN 3, LIN 4 and LIN 6 were substantially under-caught relative to their TACCs, the LIN 5 catch was just under the TACC, and the LIN 1, LIN 2 and LIN 7 TACCs were slightly over-caught. Reported landings for the main QMAs from 1931 to 1982 are given in Table 2, reported landings by nation from 1975 to 1987–88 are given in Table 3, and reported landings

LING (LIN)

by Fishstock from 1983–84 onwards are shown in Table 4. Figure 1 shows the historical landings and TACC values for the main LIN stocks.

Under the Adaptive Management Programme (AMP), the TACC for LIN 1 was increased to 400 t from 1 October 2002, and it remained at this level when LIN 1 was removed from the AMP on 30 September 2009. In a proposal for the 1994–95 fishing year, TACCs for LIN 3 and 4 were increased to 2810 and 5 720 t, respectively. These stocks were removed from the AMP from 1 October 1998, with TACCs maintained at the increased level. However, from 1 October 2000, the TACCs for LIN 3 and 4 were reduced to 2 060 and 4 200 t, respectively. From 1 October 2004, the TACCs for LIN 5 and LIN 6 were increased by about 20% to 3 595 t and 8 505 t, respectively, and the LIN 5 was increased by a further 10% (to 3 955 t) from 1 October 2013. From 1 October 2009, the TACC for LIN 7 was increased from 2 225 t to 2 474 t, and further increased to 3 080 t from 1 October 2013. All other TACC increases since 1986–87 in all stocks are the result of quota appeals.

LING (LIN)

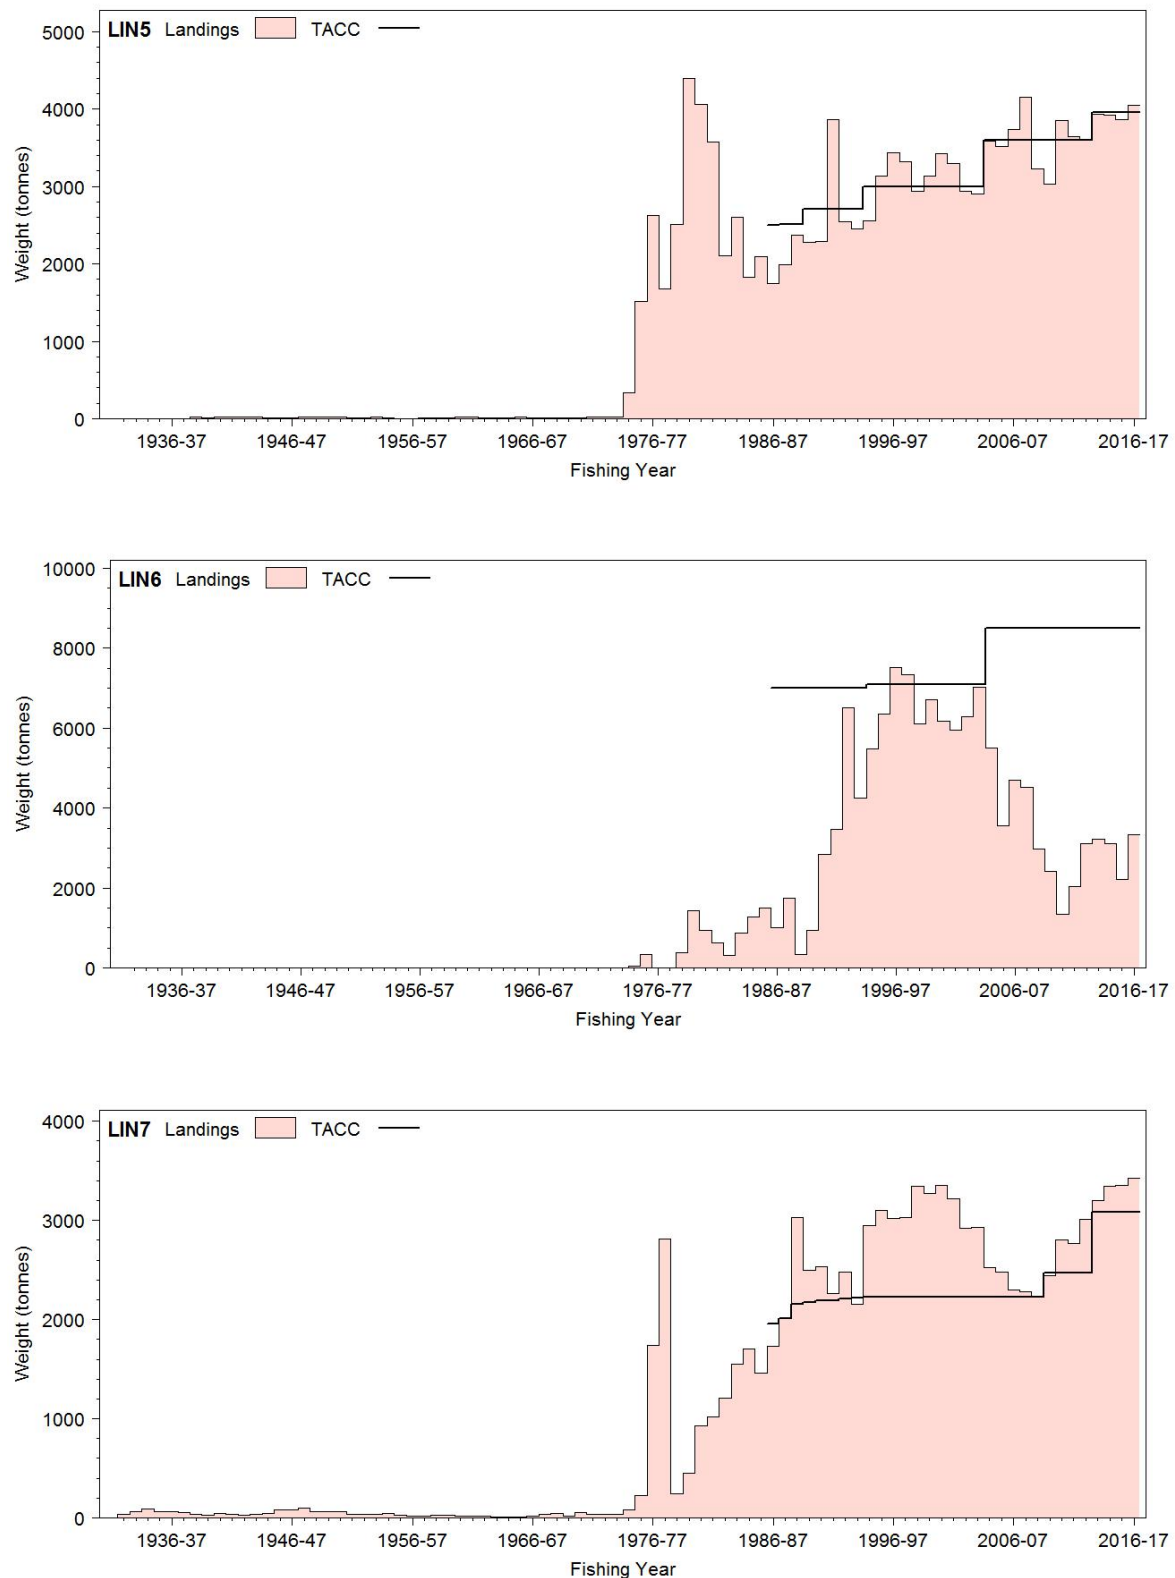

Figure 1 [continued]: Reported commercial landings and TACC for the seven main LIN stocks. From top to bottom: LIN 5 (Southland), LIN 6 (Sub-Antarctic) and LIN 7 (Challenger).

1.2 Recreational fisheries

The 1993–94 North region recreational fishing survey (Bradford 1996) estimated the annual recreational catch from LIN 1 as 10 000 fish (CV 0.23). With a mean weight likely to be in the range of 1.5 to 4 kg, this equates to a harvest of 15–40 t. Recreational catch was recorded from LIN 1, 5, and 7 in the 1996 national diary survey. The estimated harvests (LIN 1, 3000 fish; LIN 5, less than 500; LIN 7, less than 500) were too low to provide reliable estimates.

The harvest estimates provided by telephone-diary surveys between 1993 and 2001 are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. In response to these problems and the cost and scale challenges associated with onsite methods, a National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Only three fishers reported catching ling in LIN 1 (four trips) and only four fishers reported catching ling in LIN 2 (five trips) leading to estimates of 308 and 1026 fish harvested, respectively (both with very high CVs) (Wynne-Jones et al 2014).

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

Quantitative information on the level of Maori customary non-commercial take is not available. Ling bones have been recovered from archaic middens throughout the South Island and southern North Island, and on Chatham Island (Leach & Boocock 1993). In South and Chatham Islands, ling comprised about 4% (by number) of recovered fish remains.

1.4 Illegal catch

It is believed that up to the mid-1990s some ling bycatch from the west coast hoki fishery was not reported. Estimates of total catch including non-reported catch are given in Table 4 for LIN 7. It is believed that in recent years, some catch from LIN 7 has been reported against other ling stocks (probably LIN 3, 5, and 6). The likely levels of misreporting are moderate, being about 250–400 t in each year from 1989–90 to 1991–92 (Dunn 2003).

1.5 Other sources of mortality

The extent of any other sources of mortality is unknown.

2. BIOLOGY

The maximum age recorded for New Zealand ling is 46 years, although only 0.5% of successfully aged ling have been older than 30 years. A growth study of ling from five areas (west coast South Island, Chatham Rise, Bounty Plateau, Campbell Plateau, and Cook Strait) showed that females grew significantly faster and reached a greater size than males in all areas, and that growth rates were significantly different between areas. Ling grow fastest in Cook Strait and slowest on the Campbell Plateau (Horn 2005).

M was initially estimated from the equation $M = \log_e 100/\text{maximum age}$, where maximum age is the age to which 1% of the population survives in an unexploited stock. The mean M calculated from five samples of age data was 0.18 (range = 0.17–0.20) (Horn 1993). However, a recent review of M , and results of modelling conducted in 2007, suggested that this parameter may vary between stocks (Horn 2008). The M for Chatham Rise ling appears to be lower than 0.18, while for Cook Strait and west coast South Island the value may be higher than 0.18. M has been estimated in assessment model runs for some stocks (see Section 4).

Ling in spawning condition have been reported in a number of localities throughout the EEZ (Horn 2005, 2015). Time of spawning appears to vary between areas: August to October on the Chatham Rise; September to December on Campbell Plateau and Puysegur Bank; September to February on the Bounty Plateau; July to September off west coast South Island and in Cook Strait. Little is known about the distribution of juveniles until they are about 40 cm total length, when they begin to appear in trawl samples over most of the adult range.

LING (LIN)

Ling appear to be mainly bottom dwellers, feeding on crustaceans such as *Munida* and scampi and also on fish, with commercial fishing discards being a significant dietary component (Dunn et al 2010). However, they may at times be caught well above the bottom, for example when feeding on hoki during the hoki spawning season.

Biological parameters relevant to the stock assessment are shown in Table 5.

Table 5: Estimates of biological parameters. See Section 3 for definitions of Fishstocks.

3. STOCKS AND AREAS

A review of ling stock structure (Horn 2005) examined diverse information from studies of morphometrics, genetics, growth, population age structures, and reproductive biology and behaviour, and indicated that there are at least five ling stocks, i.e., west coast South Island, Chatham Rise, Cook Strait, Bounty Plateau, and the Southern Plateau (including the Stewart-Snares shelf and Puysegur Bank). Stock affinities of ling north of Cook Strait are unknown, but spawning is known to occur off Northland, Cape Kidnappers, and in the Bay of Plenty.

4. STOCK ASSESSMENT

LIN 1 was previously managed and assessed under the Adaptive Management Programme (see Section 5) and an updated CPUE analysis for this Fishstock was conducted in 2017. A CPUE analysis for the ling target bottom longline fishery in LIN 2 was conducted in 2014. The stock assessments for two ling stocks (LIN 3&4, Chatham Rise; LIN 5&6, Sub-Antarctic) were updated in 2015. Assessments for other stocks were updated in 2007 (LIN 6B, Bounty Plateau, with a CPUE update in 2014), 2013 (LIN 7CK, Cook Strait), or 2017 (LIN 7WC, west coast South Island). All assessments (excluding LIN 1 and LIN 2) were updated using a Bayesian stock model implemented using the general-purpose stock assessment program CASAL (Bull et al 2012).

4.1 Estimates of fishery parameters and abundance

Catch histories by stock and fishery are presented in Table 6, and other model input parameters are shown in Table 7. Estimates of relative abundance from standardised CPUE analyses (Table 8) and trawl surveys (Table 9) are also presented below.

Table 6: Estimated catch histories (t) for LIN 2 (ECNI), LIN 3&4 (Chatham Rise), LIN 5&6 (Campbell Plateau), LIN 6B (Bounty Platform), LIN 7WC (WCSI section of LIN 7), and LIN 7CK (Cook Strait). Landings have been separated by fishing method (trawl or line), and, for the LIN 5&6 line fishery, by pre-spawning (Pre) and spawning (Spn) season.

* Not used in the reported assessment.

4.2 East Coast North Island, (LIN 2, Statistical Areas 011–015)

In 2014 a catch-per-unit-effort (CPUE) analysis was conducted on data from the LIN 2 fishery (Roux 2015). Estimated catch data and effort data from bottom longliners that fished in FMA 2 Statistical Areas 011–015 (ECNI) targeting ling where there was a positive catch were used. The estimated catch and effort data were rolled up by vessel/day/statistical area after a filter was applied to individual fishing events to retain estimated catch from the top five species together with all effort.

A GLM model (model 1) was fitted using a core vessel fleet where individual vessels had to have fished for four or more years in the fishery, and fished a minimum of 10 days per year. One auto-longlining vessel was excluded because it was an outlier in terms of numbers of hooks set, and created patterns in the residuals.

The sensitivity of the CPUE time series was tested for a range of alternative sets of input data: vessels using very large numbers of hooks per day (over 10 000) were either included or excluded; changes in fishing power and fleet were minimised by fitting only the most recent time series (2000–2013); data from Statistical Area 016 (Cook Strait) were either included or excluded; and fitting was carried out with or without the use of interaction terms. An all-target model using bottom longline data that targeted or caught ling was also developed with ‘target species’ included as an explanatory variable. The GLM trend was robust to all sensitivities investigated.

The standardised CPUE index for ling from the ECNI demonstrates an initial decline consistent with the previous assessment (Horn 2004), followed by a period of stability (2002–2010) with lower CPUE in 2011–12 and 2012–13 (Figure 2). This pattern was consistent across all GLM scenarios examined.

Figure 2: Estimated ling catch (bars) and standardized CPUE indices for LIN 2. Blue line and triangles from Horn (2004). Red line and circles for ECNI Statistical Areas 011–015 for core bottom longline vessels targeting ling, from Roux (2015). The two CPUE series were normalised to the overlapping fishing years (1992–2001).

4.3 Chatham Rise, LIN 3 & LIN 4

4.3.1 Model structure and inputs

The stock assessment for LIN 3&4 (Chatham Rise) was updated in 2015 (McGregor 2015). For final model runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm. Bounded estimates of spawning stock virgin (B_0) and current (B_{2014}) biomass were obtained. Year class strengths and fishing selectivity ogives were estimated in the model. Trawl fishery and research survey selectivity ogives were fitted as double normal curves; line fishery ogives were fitted as logistic curves. Selectivities were assumed constant over all years in each fishery/survey. Instantaneous natural mortality (M) was estimated as a constant

in the model. MCMCs were estimated using a burn-in length of 2×10^5 iterations, with every 1000th sample kept from the next 6×10^6 iterations (i.e., a final sample of length 6000 was taken from the Bayesian posterior).

For LIN 3&4, model input data included catch histories, biomass and sexed catch-at-age data from a summer trawl survey series, sexed catch-at-age from the trawl fishery, line fishery CPUE, unsexed catch-at-age and catch-at-length from the line fishery, and estimates of biological parameters (Table 10). The catch history, biological input parameters, and estimates of relative abundance used in the model are shown in Tables 5–9. The stock assessment model partitioned the population into two sexes, and age groups 3 to 25 with a plus group. The model's annual cycle is described in Table 11.

Table 10: LIN 3&4: Summary of the relative abundance series applied in the models, including source years (Years).

Data series	Years
Trawl survey proportion at age (<i>Amaltal Explorer</i> , Dec)	1990
Trawl survey biomass (<i>Tangaroa</i> , Jan)	1992–2014
Trawl survey proportion at age (<i>Tangaroa</i> , Jan)	1992–2014
CPUE (longline, all year)	1991–2013
Commercial longline proportion-at-age (Jun–Oct)	2002–09, 2013
Commercial longline length-frequency (Jun–Oct)	1995–2002
Commercial trawl proportion-at-age (Oct–May)	1992, 1994–2013

Table 11: LIN 3&4: Annual cycle of the stock model, showing the processes taking place at each time step, their sequence within each time step, and the available observations. Fishing and natural mortality that occur within a time step occur after all other processes, with half of the natural mortality for that time step occurring before and half after the fishing mortality.

Step	Period	Processes	M^1	Age ²	Description	Observations
						%Z ³
1	Dec–Aug	Recruitment fisheries (line & trawl)	0.9	0.5	Trawl survey (summer)	0.2
					Line CPUE	0.5
					Line catch-at-age/length	
					Trawl catch-at-age	
2	Sep–Nov	Spawning and increment ages	0.1	0	–	

^{1.} M is the proportion of natural mortality that was assumed to have occurred in that time step.

^{2.} Age is the age fraction, used for determining length-at-age, that was assumed to occur by the start of that time step.

^{3.} %Z is the percentage of the total mortality in the step that was assumed to have taken place at the time each observation was made.

The error distributions assumed were multinomial for the at-age and at-length data, and lognormal for all other data. The weight assigned to each data set was controlled by the error coefficient of variation (CV). The observation-error CVs were calculated using standard formulae. An additional process error CV of 0.15 was added to the trawl survey biomass index following Francis et al (2001), and a process error CV for the line fishery CPUE was estimated at 0.15 following Francis (2011). The multinomial observation error CVs for the at-age and at-length data were adjusted using the reweighting procedure of Francis (2011).

Most priors were intended to be uninformed, and were specified with wide bounds. One exception was an informative prior for the trawl survey q . The prior on q for all the *Tangaroa* trawl surveys was estimated assuming that the catchability constant was a product of areal availability (0.5–1.0), vertical availability (0.5–1.0), and vulnerability between the trawl doors (0.03–0.40). The resulting (approximately lognormal) distribution had mean 0.13 and CV 0.70, with bounds assumed to be 0.02 to 0.30. The other exception was the normal prior on p_{male} with $\mu=0.5$, $CV=0.15$. Penalty functions were used to constrain the model so that any combination of parameters that did not allow the historical catch to be taken was strongly penalised. A penalty was applied to the estimates of year class strengths to encourage estimates that averaged to 1.

In all model runs, the catchability coefficients (q 's) were free, unless there were difficulties in convergence, in which case they were set as nuisance variables (they were integrated out). The runs that included the longline CPUE had difficulty converging.

There is a conflict between the line fishery CPUE and the trawl survey biomass index, in which the line fishery biomass index declined between 1991 and 1997, but the trawl survey index remained relatively

flat throughout. To remove this conflict, a base case model run (Base) used all the observational data except the line fishery CPUE. The trawl survey biomass index was preferred in the base case because these data were fishery independent, and there was evidence that the longline fishery q had changed over time as very large fish were removed from the population (Horn 2015). A sensitivity run (Longline) then included the line fishery CPUE, and excluded the trawl survey biomass series; this model is considered a likely ‘worst case’ scenario. Additional models included both biomass indices (All), tested logistic, rather than double normal, selectivity ogives for trawl survey and fishery (Selectivity), and estimated a separate natural mortality for each sex (M), but these models are not reported in detail here.

4.3.2 Model estimates

The fits to the biomass indices, catch-at-age and catch-at-length data, were all reasonable, and almost indistinguishable between model runs. Year class strength estimates (Figure 3) were generally average or below average since 1980, except for 1994 and 1995. Estimated year class strengths were not widely variable, with all medians being between 0.5 and 2. Ling were first caught by the trawl survey (age at full selectivity 6 years), then the trawl fishery (age 8 years), and then the line fishery (age 16 years). Selectivities for the trawl fishery and survey tended towards a logistic distribution, although a double normal distribution was offered. Males were estimated to be less vulnerable than females to the trawl fishery. The estimated median M (for sexes combined) was 0.15.

The assessment was driven by the catch history, and by catch-at-age data, which contain information indicative of a stock decline during the 1990s.

Figure 3: LIN 3&4: Estimated posterior distributions of year class strength for the base model. The horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

Although estimates of current and virgin stock size were imprecise, it was unlikely that B_0 was lower than 110 000 t for this stock, or that biomass in 2014 was less than 44% of B_0 (Table 12, Figure 4). Annual exploitation rates (catch over vulnerable biomass) were estimated to be lower than 0.15 (often much lower) since 1979 (Figure 5).

Table 12: LIN 3&4: Bayesian median and 95% credible intervals (in parentheses) of B_0 and B_{2014} (in tonnes, and as a percentage of B_0) for the Base and Longline model runs, and the probability that B_{2014} is above 40% of B_0 from the Base model run.

Model run	B_0		B_{2014}		B_{2014} (% B_0)		$P(40\% B_0)$
Base	126 600	(110 700–165 100)	71 800	(50 500–115 200)	57	(45–71)	0.003
Longline	107 400	(98 700–122 700)	60 900	(42 000–85 600)	40	(30–51)	–

The model indicated a relatively flat biomass trajectory since about 2006 (Figure 4). Annual landings from the LIN 3&4 stock have been less than 4 600 t since 2004, markedly lower than the 6 000–8 000 t taken annually between 1992 and 2003. Biomass projections derived from this assessment are shown below (Section 4.9).

Figure 4: LIN 3&4 base model: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for absolute biomass and biomass as a percentage of B_0 .

Figure 5: LIN 3&4 base model: Exploitation rates (catch over vulnerable biomass) with 95% credible intervals shown as dashed lines.

4.4 Sub-Antarctic, LIN 5 & LIN 6 (excluding Bounty Plateau)

4.4.1 Model structure and inputs

The stock assessment for LIN 5&6 (Sub-Antarctic) was updated in 2018 (Masi in prep). For final runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm. Bounded estimates of spawning stock virgin (B_0) and current (B_{2018}) biomass were obtained. Year class strengths and fishing selectivity ogives were also estimated in the model. Trawl fishery selectivity ogives were fitted as double normal curves; line fishery and research survey ogives were fitted as logistic curves. Selectivities were assumed constant over all years in each fishery/survey.

MCMC chains with a total length of 4×10^6 iterations were constructed. A burn-in length of 1×10^6 iterations was used, with every 1000th sample taken from the final 3×10^6 iterations (i.e., a final sample of length 3000 was taken from the Bayesian posterior).

For LIN 5&6, model input data include catch histories, biomass and catch-at-age data from summer and autumn trawl survey series, two line fishery CPUE series (from the spawning and home ground fisheries), catch-at-age from the spawning ground and home ground line fisheries, catch-at-age data from the trawl fishery, and estimates of biological parameters. A base case run is presented, which had a constant, estimated natural mortality with respect to age and a revised annual cycle for the spawn and non-spawn line fisheries. The stock assessment model partitions the population into two sexes, and age groups 3 to 25 with a plus group. The base model's annual cycle is described in Table 13.

Table 13: LIN 5&6: Annual cycle of the stock model, showing the processes taking place at each time step, their sequence within each time step, and the available observations. Fishing and natural mortality that occur within a time step occur after all other processes, with half of the natural mortality for that time step occurring before and half after the fishing mortality.

Step	Period	Processes	M^1	Age ²	Description	Observations %Z ³
1	Dec–Aug	Trawl and Spawning fishery (line) fisheries Increment ages	0.33	0.0	Trawl survey (summer)	0.1
					Trawl survey (autumn)	0.5
					Trawl catch-at-age	0.7
					Line CPUE (spawning)	
					Line (spawning) catch-at-age	
2	Sep–Nov	Recruitment	0.67	0.5	Line CPUE (non-spawn)	
		Non-spawning (line) fishery			Line (non-spawn) catch-at-age	0.5

^{1.} M is the proportion of natural mortality that was assumed to have occurred in that time step.

^{2.} Age is the age fraction, used for determining length-at-age, that was assumed to occur in that time step.

^{3.} %Z is the percentage of the total mortality in the step that was assumed to have taken place at the time each observation was made.

A summary of all observations used in this assessment and the associated time series is given in Table 14. Lognormal errors, with known CVs, were assumed for all relative biomass observations. The CVs available for those observations of relative abundance allow for sampling error only. However, additional variance, assumed to arise from differences between model simplifications and real world variation, was added to the sampling variance. The additional variance, termed process error was fixed to 0.11 for the base model run, following the recommendations of Francis (2011). Multinomial errors were assumed for all age composition observations. The effective sample sizes for the composition samples were estimated following method TA1.8 as described in Appendix A of Francis (2011).

Table 14: LIN 5&6: Summary of the relative abundance series applied in the models, including source years (Years).

Data series	Model Years
Trawl survey biomass (<i>Tangaroa</i> , Nov–Dec)	1992–94, 2001–10, 2012–13, 2015, 2017
Trawl survey proportion at age (<i>Tangaroa</i> , Nov–Dec)	1992–94, 2001–10, 2012–13, 2015, 2017
Trawl survey biomass (<i>Tangaroa</i> , Mar–May)	1992–93, 1996, 1998
Trawl survey proportion at age (<i>Tangaroa</i> , Mar–May)	1992–93, 1996, 1998
CPUE (longline, spawning fishery)	1991–2017
CPUE (longline, non-spawning fishery)	1991–2017
Commercial longline proportion-at-age (spawning, Oct–Dec)	2000–08, 2010, 2017
Commercial longline proportion-at-age (non-spawn, Feb–Jul)	1999, 2001, 2003, 2005, 2009–12, 2014
Commercial trawl proportion-at-age (Sep–Apr)	1992–94, 1996, 1998, 2001–17

The assumed prior distributions used in the assessment are given in Table 15. Most priors were intended to be relatively uninformed, and were specified with wide bounds. The exceptions were the choice of informative priors for the trawl survey q . The priors on q for all the *Tangaroa* trawl surveys were estimated assuming that the catchability constant was a product of areal availability (0.5–1.0), vertical availability (0.5–1.0), and vulnerability between the trawl doors (0.03–0.40). The resulting (approximately lognormal) distribution had mean 0.13 and CV 0.70, with bounds assumed to be 0.02 to 0.30.

Table 15: LIN 5&6: Assumed prior distributions and bounds for estimated parameters in the assessments. The parameters for lognormal priors are mean (in log space) and CV

Parameter description	Distribution	Parameters		Bounds	
B_0	Uniform-log	–	–	50 000	800 000
Year class strengths	Lognormal	1.0	0.70	0.01	100
Trawl survey q	Lognormal	0.13	0.70	0.02	0.3
CPUE q	Uniform-log	–	–	1e-8	1e-3
Selectivities	Uniform	–	–	0	20–200 ¹
M^2	Uniform	–	–	0.01	0.6

^{1.} A range of maximum values were used for the upper bound

^{2.} Constant, estimated natural mortality used in base model

Penalty functions were used to constrain the model so that any combination of parameters that did not allow the historical catch to be taken was strongly penalised. A small penalty was applied to the

estimates of year class strengths to encourage estimates that averaged to 1. The catch history, biological input parameters, and estimates of relative abundance used in the model are shown in Tables 5–9.

4.4.2 Model estimates

Description of the base model run reported is as follows:

The base case is considered to be a reference model, except process error for both summer and autumn trawl surveys was set to 0.11, a constant, estimated natural mortality with respect to age was applied and a revised annual cycle for the spawn and non-spawn line fisheries was used.

Five sensitivities were investigated: (1) the updated 2015 model using free q 's (hereafter referred to as the reference model) (2) using nuisance q 's, (3) logistic selectivity ogive for longline spawn only, (4) doubled the mean of the prior for q for the trawl surveys, and (5) halved multinomial weightings associated with age composition estimates. An additional trial of fitting to CPUE was investigated, however this model was found to have potential structural issues. The MPD run with the CPUE index predicted $\%B_0$ was still above the 40% threshold, but the CPUE spawn index was not adequately reflecting abundance due to a decline in catch in recent years. Therefore, there was uncertainty as to the CPUE index being a reliable measure of abundance. From the five sensitivity runs trialled, MPD estimates of stock status were between 86–94% B_0 .

Posterior distributions of year class strength estimates from the base case model run are shown in Figure 6; the distribution from the base case model differed little from the reference model. Year classes were generally weak from 1982 to 1992, strong from 1994 to 1996, 2005 to 2006, 2008 and 2010, and average since then. Overall, estimated year class strengths were not widely variable, with all medians being between 0.5 and 1.5. Consequently, biomass estimates for the stock declined through the 1990s, but have exhibited an upturn during the last 17 years (Figure 7). The biomass trajectory from the base case model was little different to that derived from the reference model.

Biomass estimates for the stock appear very healthy, with estimated current biomass from three reported models at 88–90% of B_0 (Figure 7, Table 16). Annual exploitation rates (catch over vulnerable biomass) were low (less than 0.05) in all years as a consequence of the high estimated stock size in relationship to the level of relative catches (Figure 8).

Figure 6: LIN 5&6: Estimated posterior distributions of year class strength from the base case run. The horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

Figure 7: LIN 5&6 base model: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for absolute biomass and biomass as a percentage of B_0 . The management target of 40% B_0 is represented as a solid line and the dashed line is the soft limit (20% B_0).

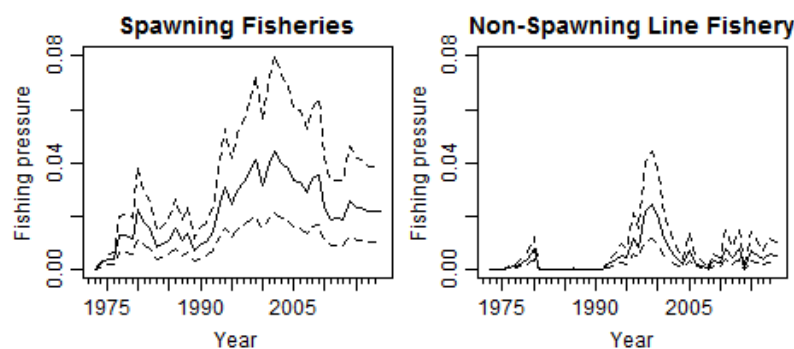

Figure 8: LIN 5&6 base model: Exploitation rates (catch over vulnerable biomass) with 95% credible intervals shown as dashed lines.

Table 16: LIN 5&6: Bayesian median and 95% credible intervals (in parentheses) of B_0 and B_{2018} (in tonnes), and B_{2018} as a percentage of B_0 , and the probability that B_{2018} is above 40% of B_0 from the Base model, Reference model and Base model with nuisance q's.

Model run		B_0		B_{2018}		$B_{2018} (\%B_0)$	$P(40\% B_0)$
Base case model	305 306	(206 265–568 452)	271 900	(164 127–498 668)	88.4	(75.4–101.1)	0.000
Reference model	278 469	(185 556–507 129)	253 822	(142 119–508 076)	90.3	(74.1–104.7)	0.000
Nuisance q's model	373 544	(233 061–657 266)	339 627	(190 132–638 935)	91.4	(79.4–103.1)	0.000

Resource survey and fishery selectivity ogives were relatively tightly defined. The survey ogive suggested that ling were fully selected by the research gear at about age 7–9. Estimated fishing selectivities indicated that ling were fully selected by the trawl fishery at about age 9 years, and by the line fisheries at about age 12–16.

The assessments indicated a biomass trough about 1999, and some recovery since then. Although estimates of current and virgin stock size are very imprecise, it is most unlikely that B_0 was lower than 200 000 t for this stock, and it is very likely that current biomass is greater than 70% of B_0 . Biomass projections derived from this assessment are shown below (Section 4.9).

4.5 Bounty Plateau, LIN 6B (Bounty Plateau only)

4.5.1 Model structure and inputs

The stock assessment for the Bounty Plateau stock (part of LIN 6) was updated in 2007 (Horn 2007b). For final runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm. Bounded estimates of spawning stock virgin (B_0) and current (B_{2006}) biomass were obtained. Year class strengths and fishing selectivity ogives were also estimated in the model. Line fishery ogives were fitted as logistic curves.

MCMC chains were constructed using a burn-in length of 5×10^5 iterations, with every 1000th sample taken from the next 10^6 iterations (i.e., a final sample of length 1000 was taken from the Bayesian posterior).

For LIN 6B, model input data include catch histories, line fishery CPUE, catch-at-age and catch-at-length from the line fishery, and estimates of biological parameters. In the absence of sufficient stock-specific data, maturity ogives were assumed to be the same as for LIN 3&4, a stock with comparable growth parameters to LIN 6B. Only a base case model run is presented. The stock assessment model partitions the population into two sexes, and age groups 3 to 35 with a plus group. There is one fishery (longline) in the stock. The model's annual cycle is described in Table 17.

Lognormal errors, with observation-error CVs, were assumed for all relative biomass, proportions-at-age, and proportions-at-length observations. Additional process error was estimated in MPD runs of the model (Table 18) and fixed in all subsequent runs.

Table 17: LIN 6B: Annual cycle of the stock model, showing the processes taking place at each time step, their sequence within each time step, and the available observations. Fishing and natural mortality that occur within a time step occur after all other processes, with half of the natural mortality for that time step occurring before and half after the fishing mortality.

Step	Period	Processes	M^1	Age ²	Description	Observations %Z ³
1	Dec–Sep	Recruitment fisher y (line)	0.9	0.5	Line CPUE Line catch-at-age/length	0.5 0.5
2	Oct–Nov	increment ages	0.1	0	–	–

^{1.} M is the proportion of natural mortality that was assumed to have occurred in that time step.

^{2.} Age is the age fraction, used for determining length-at-age, that was assumed to occur in that time step.

^{3.} %Z is the percentage of the total mortality in the step that was assumed to have taken place at the time each observation was made.

Table 18: LIN 6B: Summary of the relative abundance series applied in the models, including source years (Years), and the estimated process error (CV) added to the observation error.

Data series	Years	Process error CV
CPUE (longline, all year)	1992–2004	0.15
Commercial longline length-frequency (Nov–Feb)	1996, 2000–04	0.50
Commercial longline proportion-at-age (Dec–Feb)	2000–01, 2004	0.40

The assumed prior distributions used in the assessment are given in Table 19. All priors were intended to be relatively uninformed, and were estimated with wide bounds.

Table 19: LIN 6B: Assumed prior distributions and bounds for estimated parameters for the assessments. The parameters are mean (in log space) and CV for lognormal.

Parameter description	Distribution	Parameters		Bounds	
B_0	uniform-log	–	–	5 000	100 000
Year class strengths	lognormal	1	0.7	0.01	100
CPUE q	uniform-log	–	–	1.00E-08	1.00E-03
Selectivities	uniform	–	–	0	20–200*
Process error CV	uniform-log	–	–	0.001	2

Penalty functions were used to constrain the model so that any combination of parameters that did not allow the historical catch to be taken was strongly penalised. A small penalty was applied to the estimates of year class strengths to encourage estimates that averaged to 1.

The catch history, biological input parameters, and estimates of relative abundance used in the model are shown in Tables 5–9.

4.5.2 Model estimates

Only a base case model run was completed.

Posterior distributions of year class strength estimates from the base case model run are shown in Figure 9.

LING (LIN)

Figure 9: LIN 6B: Estimated posterior distributions of year class strength from the base case run. The horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

The assessment was driven largely by the catch-at-age and catch-at-length series from the line fishery; the first two years of CPUE data were not well fitted. Biomass estimates are listed in Table 20 and the biomass trajectory is shown in Figure 10. The assessment indicates a declining biomass throughout the history of the fishery. Estimates of current and virgin stock size are not well known, but current biomass is very likely to be above 50% of B_0 .

Table 20: LIN 6B: Bayesian median and 95% credible intervals (in parentheses) of B_0 and B_{2006} (in t), and B_{2006} as a percentage of B_0 for the base case model run.

Model run	B_0	B_{2006}	B_{2006} (% B_0)
Base case	13 570 (10 850–19 030)	8 330 (4 860–14 730)	61 (45–79)

Figure 10: LIN 6B: Estimated posterior distributions of biomass trajectories as a percentage of B_0 , from the base case model run (including 5-year projections through to 2011 with assumed constant annual catch of 400 t). Distributions are the marginal posterior distribution, with horizontal lines indicating the median.

Biomass projections derived from this assessment are shown below (Section 4.9).

4.6 West Coast South Island, LIN 7WC

4.6.1 Model structure and inputs

The stock assessment for LIN 7WC (west coast South Island) was updated in 2017 (Dunn & Ballara 2018). The assessment model partitioned the population into age groups 3 to 28 with a plus group, and immature and mature fish, with no sex in the partition. The model's annual cycle is described in Table 21.

Table 21: LIN 7WC: Annual cycle of the stock model, showing the processes taking place at each time step, their sequence within each time step, and the available observations. Fishing and natural mortality that occur within a time step occur after all other processes, with half of the natural mortality for that time step occurring before and half after the fishing mortality.

Step	Period	Processes	M^1	Age ²	Description	Observations %Z ³
1	Oct–May	Recruitment fishery (line)	0.75	0.5	Line catch-at-age	0.5
2	Jul–Sep	increment ages fishery (trawl)	0.25	0	Trawl survey biomass and catch at age Trawl catch-at-age Trawl CPUE	0.5

1. M is the proportion of natural mortality that was assumed to have occurred in that time step.

2. Age is the age fraction, used for determining length-at-age, that was assumed to occur in that time step.

3. %Z is the percentage of the total mortality in the step that was assumed to have taken place at the time each observation was made.

The reported model runs were developed following the investigation of numerous previous model runs. These evaluated the sensitivity of the model fit to assumptions such as growth rate, natural mortality rate, CPUE index, the *Tangaroa* biomass survey q prior, inclusion of the *Kaharoa* inshore trawl survey, trawl survey and fishery selectivity ogives, weights assigned to different observational data sets, the priors on year class strength estimates, and the choice of stock-recruitment model.

Year class strengths and fishing selectivity ogives were estimated in the model. Commercial trawl fishery and mature fish research trawl survey selectivities were fitted as double normal curves; the line fishery ogive was fitted as a logistic curve. The selectivity of immature fish by the research trawl survey was estimated as a capped logistic curve.

For final runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm. Bounded estimates of spawning stock virgin (B_0) and current (B_{2017}) biomass were obtained. MCMC chains were constructed using a burn-in length of 1×10^6 iterations, with every 1000th sample taken from the next 20×10^6 iterations (i.e., a final sample of length 1000 was taken from the Bayesian posterior). Multiple chain convergence tests were applied to determine the acceptability of the estimates. The final model runs (Section 4.6.2) were considered acceptable for providing management advice. The lower bound of the biomass distributions appeared well determined, however the upper bounds were highly uncertain.

For LIN 7WC, model input data included catch histories, trawl fishery CPUE, extensive catch-at-age data from the trawl fishery, sparse catch-at-age data from the line fishery, biomass estimates and proportion-at-age from *Tangaroa* surveys in 2000, 2012, 2013, and 2016, and estimates of constant biological parameters (Table 22). A line fishery CPUE series was available, but was rejected as unlikely to be indexing stock abundance. The *Kaharoa* inshore trawl survey biomass estimates and proportion-at-length estimates were also available, but rejected because few ling older than age nine were caught in surveys, and inclusion of the data made negligible contribution to the estimation of model parameters.

The error distributions assumed were multinomial for the proportions-at-age and lognormal for all other data. Biomass indices had assumed CVs set equal to the sampling CV plus an additional process error of 0.4, estimated following Francis (2011). The multinomial observation error effective sample sizes for the trawl fishery at-age data were adjusted using the reweighting procedure of Francis (2011). An *ad hoc* procedure was used for the at-age data from the line fishery and *Tangaroa* survey at-age data, giving the line fishery a relatively low weighting, and the trawl survey a relatively high weighting.

Table 22: LIN 7WC: Summary of the relative abundance and stock composition series applied in the models, including source years (Years).

Data series	Years
CPUE (hoki trawl, Jun–Sep)	1987–2016
Commercial trawl proportion-at-age (Jun–Sep)	1991, 1994–2008, 2012–2015
Commercial longline proportion-at-age	2003, 2006, 2007, 2012, 2015
Trawl survey biomass (<i>Tangaroa</i> , July)	2000, 2012, 2013, 2016
Trawl survey age data	2000, 2012, 2013, 2016

The assumed prior distributions used in the assessment are given in Table 23. Most priors were intended to be relatively uninformed, and were specified with wide bounds. The prior for the survey q was informative and was estimated using the Sub-Antarctic ling survey priors as a starting point (see Section 4.4.1) because the survey series in both areas used the same vessel and fishing gear. However, the WCSI survey area in the 200–650 m depth range in strata 0004 A–C and 0012 A–C comprised 6619 km²; seabed area in that depth range in the entire LIN 7 WC biological stock area (excluding the Challenger Plateau) is estimated to be about 20 100 km². So, because biomass from only 33% of the WCSI ling habitat was included in the indices, the Sub-Antarctic prior on μ was modified accordingly (i.e., $0.13 \times 0.33 = 0.043$), and the bounds were also reduced from [0.02, 0.30] to [0.01, 0.20]. The prior for M was informed and based on expert opinion. Priors for all selectivity parameters were assumed to be uniform.

Table 23: LIN 7WC: Assumed prior distributions and bounds for parameters estimated in the models. For lognormal distributions the figures are the logspace mean and the CV, and for normal distributions the figures are the mean and standard deviation.

Parameter description	Distribution	Parameters		Bounds	
B_0	uniform-log	–	–	10 000	500 000
Year class strengths	lognormal	1.0	0.7	0.01	100
<i>Tangaroa</i> survey q	lognormal	0.043	0.70	0.01	0.2
CPUE q	uniform-log	–	–	1e-8	1e-3
Selectivities	uniform	–	–	0	30–200*
M	normal	0.20	0.025	0.1	0.3

* A range of maximum values was used for the upper bound.

Penalty functions were used to constrain the model so that any combination of parameters that did not allow the historical catch to be taken was strongly penalised. A small penalty was applied to the estimates of year class strengths to encourage estimates that averaged to 1.

The catch history, biological input parameters, and estimates of relative abundance used in the model are shown in Tables 5–9.

4.6.2 Model estimates

MCMC runs of three alternative models were conducted, assuming different CPUE indices and M assumptions (Table 24). There was no accepted ‘base’ case, rather the three model runs were chosen to represent the key alternative assumptions, and the range of model outcomes. The alternative CPUE indices were a ‘combined’ index, where CPUE was estimated as the product of the probability of catching ling and, when ling were caught, the catch, or a ‘lognormal’ index, where only the positive ling catch data were used. The runs either estimated M , or assumed it to be fixed at 0.18.

Posterior distributions of year class strength estimates from the Combined CPUE model run are shown in Figure 11. The YCS distribution from the other runs were not visually different and are not shown.

Figure 11: LIN 7WC: Estimated posterior distributions of year class strength for the Combined CPUE model run. The horizontal dashed line indicates a year class strength of one. Individual boxes show for each estimated cohort the median (solid horizontal line), inter-quartile range (box; half of the estimates were within this range), and overall range of estimates (broken vertical lines).

All model runs were indicative of a B_0 greater than about 60 000 t (Table 24). The upper bound on B_0 was highly uncertain and largely dependent on the weight assigned to the trawl survey proportions-at-age, and the prior on M . The Combined CPUE model run indicated a biomass decline until 1992, followed by fluctuating but stable biomass until 2016, whereas the Lognormal CPUE model runs both indicated slow overall biomass declines (Figure 12). The model fit to the trawl survey biomass series was good, but to the CPUE series (both lognormal and combined indices) was poor (Figure 13). All model runs estimated recent trawl and longline fishing pressure to be stable (Figure 14). All model runs estimated a period of higher recruitment around 1990, and in several years since 2001 (Figure 11); the relatively strong year classes since 2001 were estimated to have started recruiting to the fishery from around 2010 (at age nine).

Table 24: LIN 7WC: Bayesian median and 95% credible intervals (in parentheses) of B_0 and B_{2017} (in tonnes), and B_{2017} as a percentage of B_0 for all model runs.

Model run	B_0		B_{2017}		$B_{2017} (\%B_0)$	
Combined CPUE	99 300	(63 500–198 200)	77 400	(39 600–183 000)	79	(61–96)
Lognormal CPUE	69 300	(51 600–122 000)	46 300	(26 100–98 000)	66	(50–83)
Lognormal CPUE and $M = 0.18$	62 800	(48 900–114 500)	34 000	(19 500–84 100)	54	(39–74)

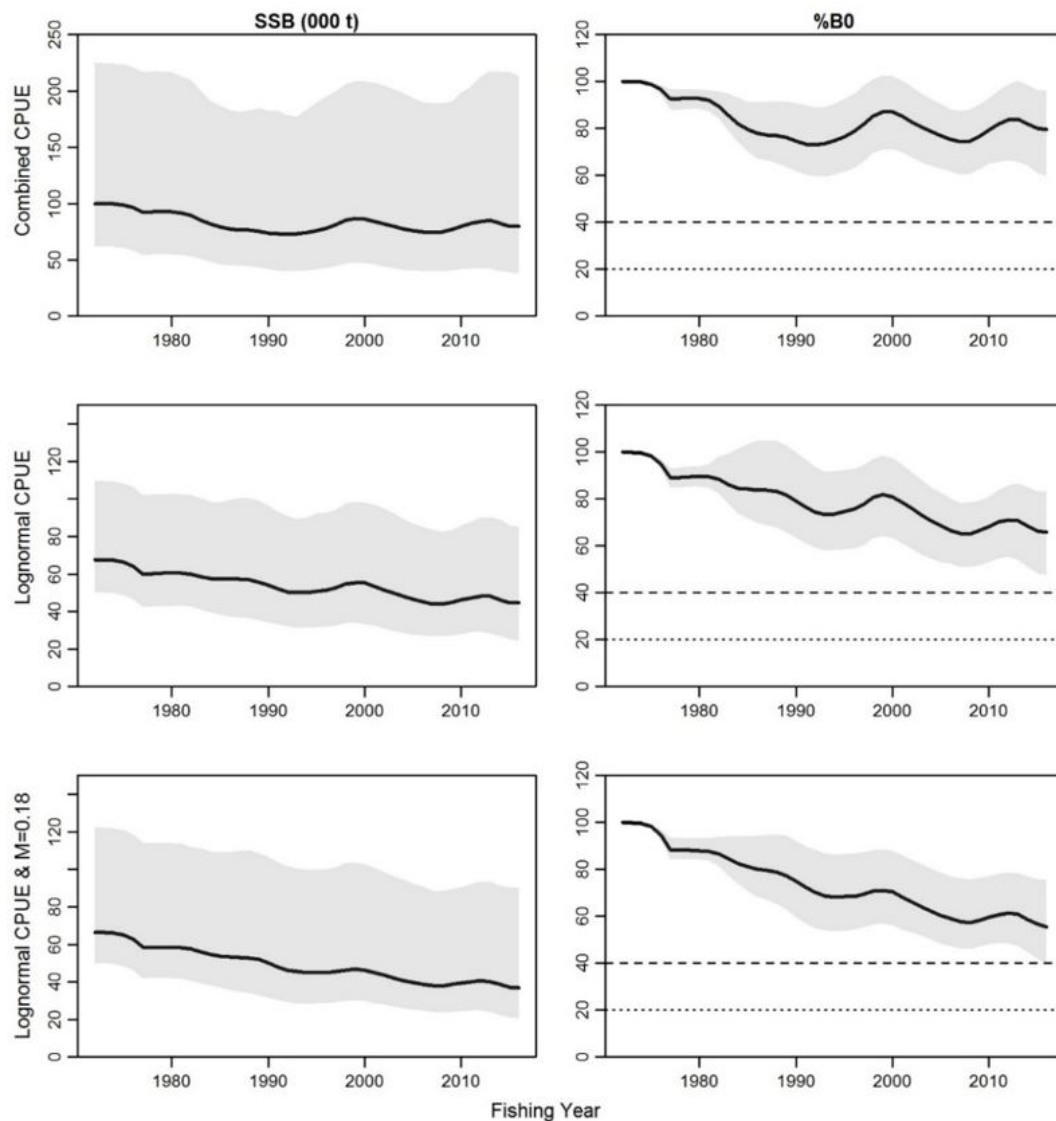

Figure 12: LIN 7WC: Estimated posterior distributions of the spawning stock biomass (t) trajectory and $\% B_0$ for the three model runs. The solid lines are the median values and the shaded area the 95% CIs.

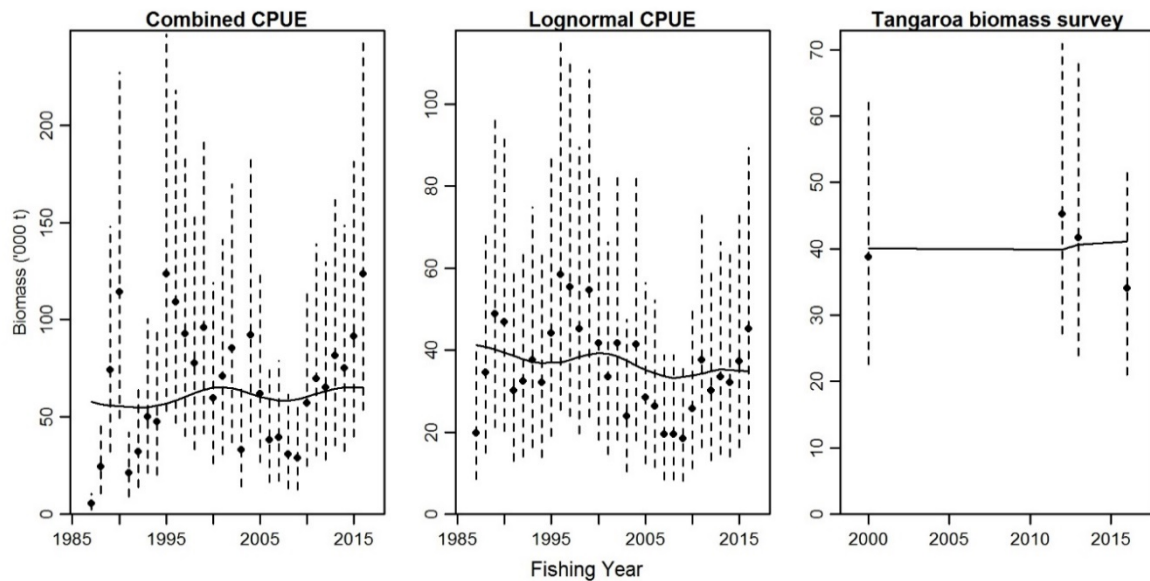

Figure 13: LIN 7WC: The fit (MPD; lines) of the Combined CPUE and Lognormal CPUE model runs to the alternative CPUE indices (solid points; vertical lines show 95% CI). The CPUE index has been scaled to the biomass using the estimated q .

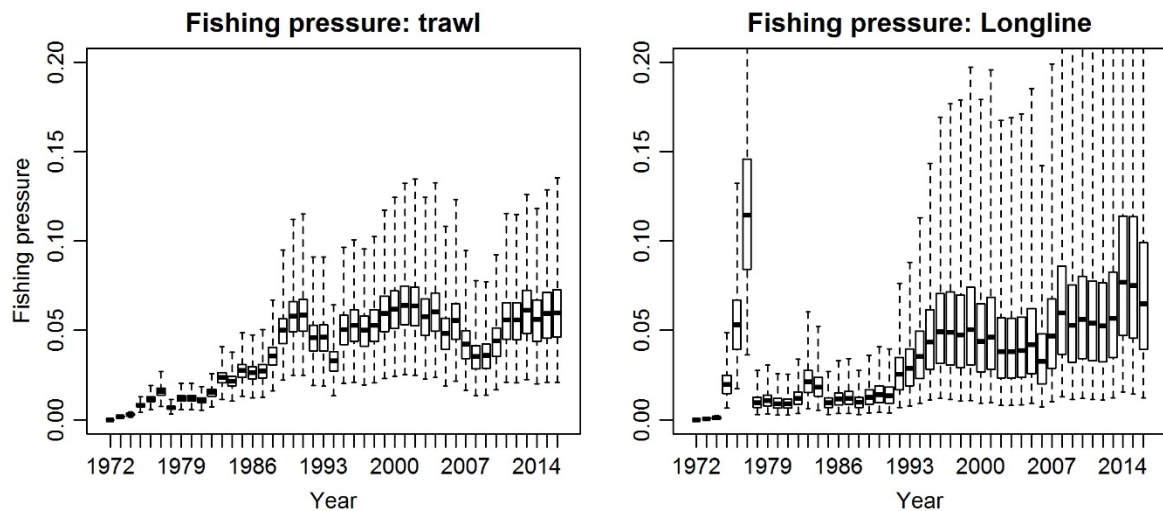

Figure 14: LIN 7WC: Estimated posterior distributions of the fishing pressure for the trawl and longline fleets, for the Combined CPUE model run. For each estimated year the pots show the median (solid horizontal line), inter-quartile range (box; half of the estimates were within this range), and overall range of estimates (broken vertical lines). Note that the y-axis has been truncated at 0.2 in these plots.

4.7 Cook Strait, LIN 7CK

4.7.1 Model structure and inputs

A stock assessment of ling in Cook Strait (LIN 7CK) was completed in 2013 (Dunn et al 2013). Because it is believed that the true M for the Cook Strait stock is higher than the 'default' value of 0.18, it was considered desirable to estimate M in the model, and so incorporate the effect of this uncertainty in M in the assessment. However, the simultaneous estimation of B_0 and M was not successful owing to the adoption of a multinomial likelihood (rather than lognormal) for proportions-at-age. Consequently, models with fixed M values were run, and although the age data were reasonably well fitted, the model failed to accurately represent declines in resource abundance that appear evident from CPUE values, which have been declining since 2001. As a consequence the model was considered unsuitable for the provision of management advice.

The last stock assessment for LIN 7CK (Cook Strait) accepted by the Working Group was completed in 2010 (Horn & Francis 2013), and it is reported here. The stock assessment model partitions the population into two sexes, and age groups 3 to 25 with a plus group. The model's annual cycle is

described in Table 25. Year class strengths and fishing selectivity ogives were also estimated in the model. Commercial trawl selectivity was fitted as double normal curves; line fishery ogives were fitted as logistic curves.

For final runs, the full posterior distribution was sampled using Markov Chain Monte Carlo (MCMC) methods, based on the Metropolis-Hastings algorithm. Bounded estimates of spawning stock virgin (B_0) and current (B_{2008}) biomass were obtained. MCMC chains were constructed using a burn-in length of 4×10^6 iterations, with every 2000th sample taken from the next 20×10^6 iterations (i.e., a final sample of length 1000 was taken from the Bayesian posterior).

For LIN 7CK, model input data include catch histories, trawl and line fishery CPUE, extensive catch-at-age data from the trawl fishery, sparse catch-at-age data from the line fishery, and estimates of biological parameters. Initial modelling investigations found that the line CPUE produced implausible results; this series was rejected as a useful index. The base case used all catch-at-age data from the fisheries, and the trawl CPUE series. Instantaneous natural mortality was estimated in the model.

Lognormal errors, with observation-error CVs, were assumed for all CPUE and proportions-at-age observations. Additional process error, assumed to arise from differences between model simplifications and real world variation, was added to the sampling variance (Table 26).

Table 25: LIN 7CK: Annual cycle of the stock model, showing the processes taking place at each time step, their sequence within each time step, and the available observations. Fishing and natural mortality that occur within a time step occur after all other processes, with half of the natural mortality for that time step occurring before and half after the fishing mortality.

Step	Period	Processes	M^1	Age ²	Description	Observations %Z ³
1	Oct–May	Recruitment fishery (line)	0.67	0.5	Line CPUE Line catch-at-age	0.5
2	Jun–Sep	increment ages fishery (trawl)	0.33	0	Trawl CPUE Trawl catch-at-age	0.5

1. M is the proportion of natural mortality that was assumed to have occurred in that time step.

2. Age is the age fraction, used for determining length-at-age, that was assumed to occur in that time step.

3. %Z is the percentage of the total mortality in the step that was assumed to have taken place at the time each observation was made.

Table 26: LIN 7CK: Summary of the available data including source years (Years), and the estimated process error (CV) added to the observation error.

Data series	Years	Process error CV
CPUE (hoki trawl, Jun–Sep)	1994–2009	0.2
Commercial trawl proportion-at-age (Jun–Sep)	1999–2009	1.1
Commercial longline proportion-at-age	2006–07	1.1

The assumed prior distributions used in the assessment are given in Table 27. Most priors were intended to be relatively uninformed, and were specified with wide bounds.

Table 27: LIN 7CK: Assumed prior distributions and bounds for estimated parameters in the assessments. The parameters are mean (in log space) and CV for lognormal, and mean and standard deviation for normal.

Parameter description	Distribution	Parameters		Bounds	
B_0	uniform-log	–	–	2 000	60 000
Year class strengths	lognormal	1.0	0.9	0.01	100
CPUE q	uniform-log	–	–	1e-8	1e-2
Selectivities	uniform	–	–	0	20–200*
M	lognormal	0.18	0.16	0.1	0.3

* A range of maximum values was used for the upper bound

Penalty functions were used to constrain the model so that any combination of parameters that did not allow the historical catch to be taken was strongly penalised. A small penalty was applied to the estimates of year class strengths to encourage estimates that averaged to 1.

The catch history, biological input parameters, and estimates of relative abundance used in the model are shown in Tables 5–9.

4.7.2 Model estimates

A single model was presented incorporating a catch history, trawl and line fishery catch-at-age, trawl CPUE series, with double-normal ogives for the trawl fishery and logistic ogives for the line fishery, and M estimated in the model.

Posterior distributions of LIN 7CK year class strength estimates from the base case model run are shown in Figure 15.

Figure 15: LIN 7CK: Estimated posterior distributions of year class strength. The horizontal line indicates a year class strength of one. Individual distributions show the marginal posterior distribution, with horizontal lines indicating the median.

The assessment is driven by the trawl fishery catch-at-age data and tuned by the trawl CPUE. Both input series contain information indicative of an overall stock decline in the last two decades. The confidence bounds around biomass estimates are wide (Table 28, Figure 16). Probabilities that current and projected biomass will drop below selected management reference points are shown in Table 29. Median M was estimated to be 0.24 (95% confidence interval 0.16–0.30). Estimates of biomass are very sensitive to small changes in M , but clearly there is information in the model encouraging an M higher than the ‘default’ value of 0.18. The model indicated a slight overall biomass decline to about 2000, followed by a much steeper decline from 2000 to 2010. Exploitation rates (catch over vulnerable biomass) were very low up to the late 1980s, and have been low to moderate (up to about 0.12 yr⁻¹) since then. Since the early 1990s, trawl fishing pressure has generally declined, while line pressure has generally increased.

Table 28: LIN 7CK: Bayesian median and 95% credible intervals (in parentheses) of B_0 and B_{2010} (in tonnes), and B_{2010} as a percentage of B_0 for all model runs.

Model run	B_0		B_{2010}		B_{2010} (% B_0)
Base case	8 070	(5 290–53 080)	4 370	(1 250–40 490)	54 (23–80)

Table 29: LIN 7CK: Probabilities that current (B_{2010}) and projected (B_{2015}) biomass will be less than 40%, 20% or 10% of B_0 . Projected biomass probabilities are presented for two scenarios of future annual catch (i.e., 220 t, and 420 t).

Biomass	Management reference points		
	40% B_0	20% B_0	10% B_0
B_{2010}	0.248	0.006	0.000
B_{2015} , 220 t catch	0.179	0.010	0.000
B_{2015} , 420 t catch	0.328	0.094	0.019

Figure 16: LIN 7CK: Estimated median trajectories (with 95% credible intervals shown as dashed lines) for absolute biomass and biomass as a percentage of B_0 .

Estimates of biomass projections derived from this assessment are shown below (Section 4.9).

4.8 LIN 1

In October 2002, the TACC for LIN 1 was increased from 265 t to 400 t within an Adaptive Management Plan (AMP). Reviews of the LIN 1 AMP were carried out in 2007 and 2009. The AMP programme was discontinued by the Minister of Fisheries in 2009–10. An update of the LIN 1 CPUE analyses was commissioned by MPI in 2013 and again in 2017, the latter is reported here.

4.8.1 Fishery Characterisation

- 51% of LIN 1 landings come from the bottom longline fishery and a further 47% by bottom trawl fishery from 1989–90 to 2015–16. The remaining methods account for less than 1.5% of the total landings. These ratios are changing, with longline landings exceeding 60% of the catch after 2012–13 and trawl landings dropping to below 40% of the catch in the same years.
- Most BT and BLL landings come from the Bay of Plenty. The majority of bottom trawl catches are taken in Statistical Areas 008 to 010, although there have been significant bottom trawl catches of ling on the west coast of the North Island in Areas 046 to 048. There were substantial ling by-catches made by trawl on the North Island west coast from 1996–97 to 2000–01 in the gemfish fishery (which has since ceased), and longline catches have increased from the East Northland area.
- Ling are caught in small quantities across many fisheries. The distribution of BT effort is broader than the distribution of catch, with effort taking some LIN 1 in East Northland and the west coast in most years. Bottom longline landings of LIN 1 have a wider distribution and are more sporadic, with the Bay of Plenty landings coming primarily from Areas 009 and 010.
- Bottom trawl catches of LIN1 are mainly made in the scampi and gemfish targeted fisheries and recently in growing hoki, tarakihi and ling target fisheries. The bycatch of ling in the gemfish fishery has considerably diminished with the reduction of the SKI 1 TACC after a peak period from 1996–97 to 2000–01. The Bay of Plenty scampi fishery has also changed, particularly after SCI entered the QMS, moving from a competitive fishery requiring multiple vessels to a more rationalised fishery requiring only a single vessel. In contrast, about 75% of the ling longline catch is taken in a targeted ling fishery, with only minor by-catches coming from bluenose, ribaldo and hapuku targeted longline fisheries.
- The bottom longline landings of LIN 1 are taken mainly in the final two months of the fishing year, probably due to the economics of the vessels switching from tuna longlining to cleaning up available quota at the end of the fishing year. Bottom trawl catches of ling tend to be more evenly distributed across the year and reflect the fishing patterns of the diverse trawl targets, such as scampi which is also a consistent fishery over the entire year. Both of the major fishing methods which take ling have sporadic seasonal patterns, reflecting the small landings in most years and the by-catch nature of many of the fisheries.
- The depth distribution of ling catches in the trawl fisheries shows two main depths associated with the target species. Most ling are caught in the scampi / hoki / ling fishery at about 400 m depth, but some are taken in the tarakihi / snapper / barracouta / trevally fisheries around 100 m depth. Bottom longline depth records indicate that target ling fishing (as well as target bluenose fishing) takes place at even deeper depths, with most of the records lying between 500 and 600 m.

Figure 17: LIN 1 CPUE analyses based on target ling bottom longline data stratified by day, assigning the modal target species and statistical area to that day. Data were restricted to Statistical Areas 002, 003, 004, 008, 009 and 010 and standardised with respect to fishing year, vessel, month and statistical area. As ling is target species, there are no records with zero catch and only the Weibull model is presented. Fishing years 1989–90 and 1990–91 are omitted because of lack of data and 1999–2000 is omitted per agreement of the Working Group because of non-representativeness of the data in that year.

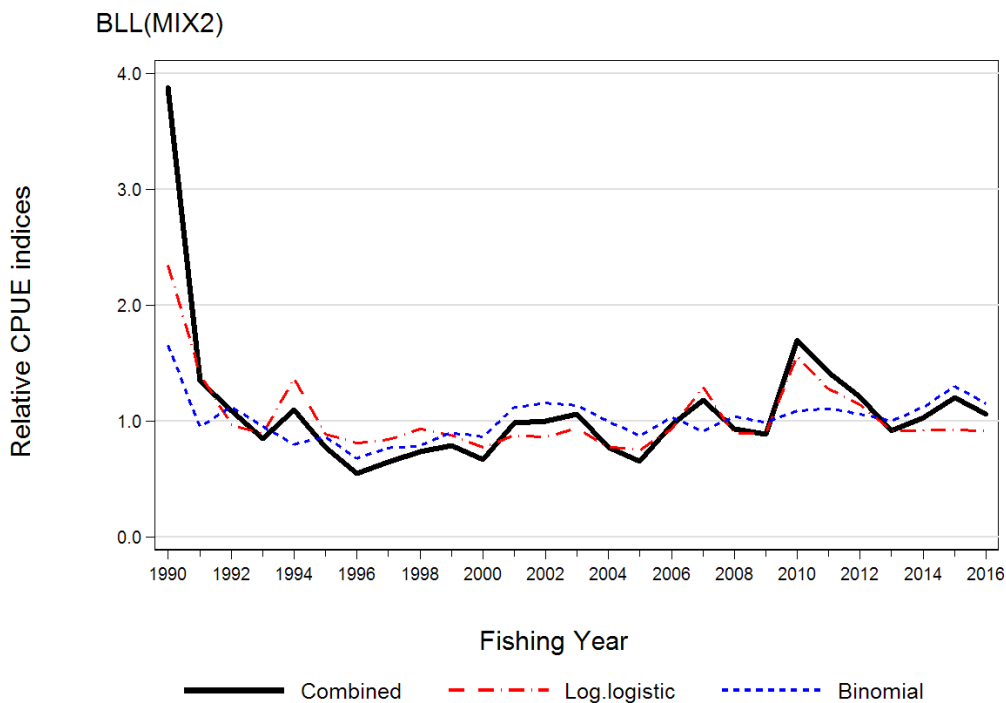

Figure 18: LIN 1 CPUE analyses based on ling bottom longline data stratified by day, assigning the modal target species and statistical area to that day. Data were restricted to Statistical Areas 002, 003, 004, 008, 009 and 010 and standardised with respect to fishing year, target species, vessel, month and statistical area. Three sets of standardised indices are presented: a) a positive catch series using the log.logistic distribution to predict $\log(\text{catch}/\text{day})$; b) a binomial series predicting catch success per day; c) a combined series, using the delta-lognormal method (Vignaux 1994) to combine the log.logistic and binomial series.

4.8.2 Abundance Indices

In 2009, the Working Group concluded that the BT(SCI) index was not an appropriate index for LIN 1, and had numerous shortcomings related to limited number of vessels, particularly in the most recent 4 years and poor linkage across years. In 2013, the NINSWG agreed with these conclusions, which also applied to the alternative BT(LINHOK, TAR) series developed in response to a 2009 Working Group recommendation. Consequently the NINSWG agreed that neither BT series was adequate for monitoring LIN 1 CPUE and should be discarded. The Working Group requirement that CPUE index values should be determined by at least 3 vessels furthermore resulted the discarding of a large number of index values from both BT series.

In 2009, the Working Group concluded that the BLL(LIN) target index appeared to have more potential as an index for LIN 1, but thought that the anomalous peak in 1998–99 was troubling and was also concerned about the relatively small amount of data in this analysis. Closer examination of the data in 2013 showed that the anomalous 1998–99 peak was caused by a small amount of very localised fishing by two experienced vessels. The NINSWG concluded that this pattern was non-representative of the fishery and the standardisation model was unable to use these data to estimate a credible year index. While this solved the mystery of the “anomalous 1998–99 index”, the problem of very small amount of data in this analysis remains. The NINSWG tentatively accepted in 2013 the BLL(LIN) index with the 1998–99 index value removed as an index of LIN 1 abundance with a research quality ranking of “2” (Figure 17).

When this series was updated in 2017, the Plenary additionally accepted a new bottom longline standardised series (BLL(MIX2), spanning four target species and operating in East Northland and the Bay of Plenty, as an abundance series for LIN 1. Both series were accepted with a quality ranking of “2” because of the sparseness of the data and the strong standardisation effect in both series. The inclusion of more target species greatly increased the amount of data in the BLL(MIX2) analysis, allowing for two earlier years to be incorporated and obviating the need to drop the anomalous peak in 1998–99. However, this analysis had a high proportion of fishing days without ling in the estimated catch: consequently a binomial presence/absence series was estimated from the data set and combined with a log.logistic positive catch series using the delta-lognormal method (Vignaux 1994). The Plenary dropped the 1989–90 index year in the BLL(MIX2) series where there was a four-fold drop between the first and second years of the series, a drop that was considered unlikely to have been caused by a corresponding drop in abundance.

4.9 Projections

Projections for LIN 6B from the 2006 assessment are shown in Table 30. The LIN 6B stock (Bounty Plateau) was projected to decline out to 2011, but probably still be higher than 50% of B_0 . Projections out to 2015 for LIN 7CK indicated that biomass was likely to increase with future catches equal to recent previous catch levels, or decline slightly if catches were equal to the mean since 1990 (Table 31). New projections made in 2014 out to 2019 for LIN 3&4 and 5&6 are shown in Table 32. For LIN 3&4, stock size is likely to remain about the same assuming future catches equal to recent catch levels, or decrease to around 90% of the 2018 biomass by 2023 if catches reach the TACC. For LIN 5&6, the probability of B_{2019} being below 40% of B_0 is very small when assuming either one of two future annual catch scenarios (the recent catch level of 6650 t or the TACC of 12 100 t). Projections out to 2022 for LIN 7WC indicated that biomass was likely to remain about the same with future catches equal to the average of catch in 2012–2016 (2980 t), or if catches for LIN 7WC were to increase modestly (by around 10%, 3300 t) to the overall LIN 7 fishstock level (Table 33).

Table 30: LIN 6B Bayesian median and 95% credible intervals (in parentheses) of projected B_{2011} , B_{2011} as a percentage of B_0 , and B_{2011}/B_{2006} (%) for the 2006 base case.

Stock and model run		Future catch (t)		B_{2011}	B_{2011} (% B_0)	B_{2011}/B_{2006} (%)

5. STATUS OF THE STOCKS

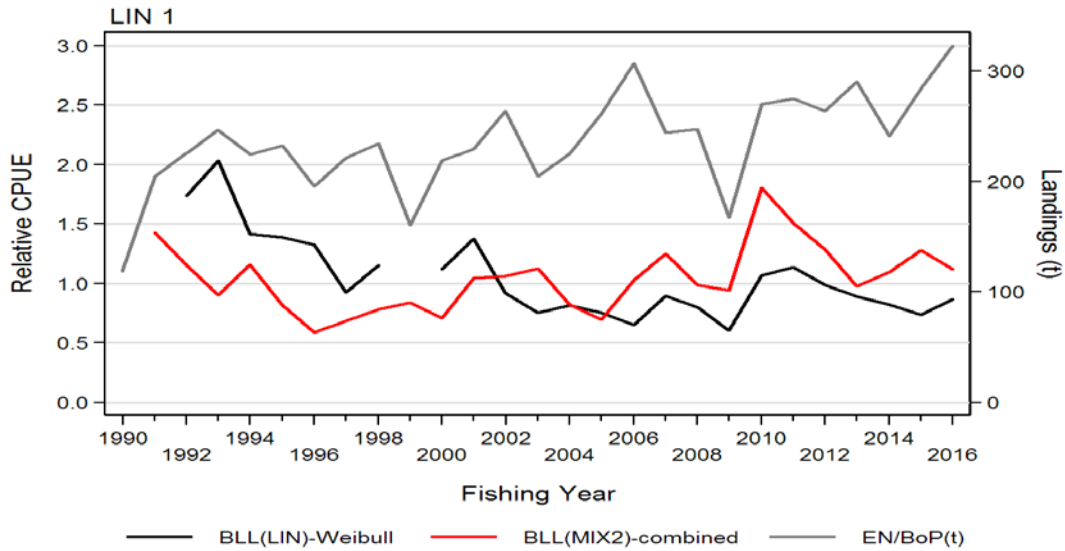

Stock Structure Assumptions

Ling are assessed as six independent biological stocks, based on the presence of spawning areas and some differences in biological parameters between areas (Horn 2005).

The Chatham Rise biological stock comprises all of Fishstock LIN 4, and LIN 3 north of the Otago Peninsula. The Sub-Antarctic biological stock comprises all of Fishstock LIN 5, all of LIN 6 excluding the Bounty Plateau, and LIN 3 south of the Otago Peninsula. The Bounty Plateau (part of Fishstock LIN 6) holds another distinct biological stock. The WCSI biological stock occurs in Fishstock LIN 7 west of Cape Farewell. The Cook Strait biological stock includes those parts of Fishstocks LIN 7 and LIN 2 between the northern Marlborough Sounds and Cape Palliser. Ling around the northern North Island (Fishstock LIN 1) are assumed to comprise another biological stock, but there is no information to support this assumption. The stock affinity of ling in LIN 2 between Cape Palliser and East Cape is unknown.

East and west coast LIN 1 are regarded as separate stocks for the purpose of this assessment.

- LIN 1 East coast only

Stock Status

Assessment Runs Presented	<ul style="list-style-type: none"> - Standardised Bottom Longline target LIN CPUE, operating in East Northland or the Bay of Plenty Weibull positive catch model - Standardised Bottom Longline CPUE targeting LIN, BNS, RIB or HPB and operating in East Northland or the Bay of Plenty (BLL MIX2); combined log.logistic (positive catches) and binomial (probability of capture)
Reference Points	Target: Not defined Soft Limit: Not defined Hard Limit: Not defined Overfishing threshold: Not defined
Status in relation to Target	Unknown
Status in relation to Limits	Unknown
Status in relation to Overfishing	Unknown
Historical Stock Status Trajectory and Current Status	
 <p>Comparison of the Weibull BLL(LIN) CPUE series and the combined BLL(MIX2) CPUE series with the East Northland/Bay of Plenty landings for LIN 1. The 1990 index year for the BLL(MIX2) series has been omitted. The two CPUE series have been standardised to a common geometric mean.</p>	

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	The BLL(MIX2) CPUE series has been gradually increasing since the mid-1990s, while the other has been relatively stable.
Recent Trend in Fishing Intensity or Proxy	Fishing intensity has fluctuated without trend since 2012
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Not evaluated
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown

LING (LIN)

Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unknown
---	---------

Assessment Methodology and Evaluation		
Assessment Type	Level 2 – Partial Quantitative Stock Assessment	
Assessment Method	CPUE analyses	
Assessment Dates	Latest assessment: 2017	Next assessment: Unknown
Overall assessment quality rank	2 – Medium or Mixed Quality: based on Medium or Mixed Quality CPUE indices	
Main data inputs (rank)	- Bottom longline target LIN CPUE series, operating in East Northland or the Bay of Plenty Weibull positive catch model - Bottom longline CPUE series, target LIN, BNS, HPB and RIB, East Northland, Bay of Plenty LIN 1 statistical areas	2 – Medium or Mixed Quality: poor vessel continuity and sparse data 2 – Medium or Mixed Quality: strong impact of target species on standardisation
Data not used (rank)	Two bottom trawl CPUE series: - SCI target - combined LIN, HOK, TAR target	3 – Low Quality: do not track stock biomass and lack data
Changes to Model Structure and Assumptions	- Additional new time series with range of target species developed	
Major Sources of Uncertainty	- Large area spanning two coasts with multiple fisheries with small catches	

Qualifying Comments
The accepted indices of abundance are based on longline fisheries operating only on the east coast of the upper North Island (East Northland and Bay of Plenty).

Fisheries Interactions
The top five species (excluding ling) that are recorded among the estimated catch of trawl trips associated with LIN 1 are snapper, trevally, tarakihi, gurnard and orange roughy. The top five species (excluding ling) that are recorded among the estimated catch of bottom longline trips associated with LIN 1 are bluenose, hapuku, school shark, ribaldo and bass. Interactions with other species are currently being characterised.

- East coast North Island (part of LIN 2, Statistical Areas 011–015)

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	CPUE time series based on bottom longline ling target fishing
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: F corresponding to 40% B_0
Status in relation to Target	Unknown. CPUE has declined by between about 50–60% since the start of the time series in 1992
Status in relation to Limits	B_{2014} is Unlikely (< 40%) to be below the Soft Limit and Very Unlikely (< 10%) to be below the Hard Limit
Status in relation to Overfishing	Unknown

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass is estimated to have declined from 1992 by 50–60%.
Recent Trend in Fishing Intensity or Proxy	Unknown
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis (2014)	
Stock Projections or Prognosis	Unknown
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown
Probability of Current Catch or TACC causing Overfishing to continue or to commence	CPUE has declined while catches have been below the TACC. There is some probability that fishing at the TACC or current catch may lead to overfishing.

Assessment Methodology and Evaluation		
Assessment Type	Level 2 – Partial Quantitative Stock Assessment	
Assessment Method	Evaluation of a CPUE time series from 1992–2013 for bottom longliners targeting ling in statistical areas 11–15.	
Assessment Dates	Latest assessment: 2014	Next assessment: Unknown
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Bottom longline effort and estimated catch	1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- It is assumed that the longline CPUE time series tracks the entire biomass of ling in this stock. - The boundaries of this biological stock, particularly towards Cook Strait, are uncertain.	

Qualifying Comments

-

Fishery Interactions

Ling are often taken as a bycatch in hoki target trawl fisheries. Target line fisheries for ling have the main bycatch species of spiny dogfish, sea perch, sharks and skates, and ribaldo. Low productivity species taken as incidental bycatch include sharks and skates. Incidental captures of protected species are reported for seabirds.

- **Chatham Rise (LIN 3 & 4)**

Stock Status

Year of Most Recent Assessment	2014
Assessment Runs Presented	One base case
Reference Points	Management Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $U_{40\%}$
Status in relation to Target	B_{2014} was estimated to be about 57% B_0 ; Very Likely (> 90%) to be above the target
Status in relation to Limits	B_{2014} is Exceptionally Unlikely (< 1%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Overfishing is Very Unlikely (<10%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the Chatham Rise ling stock from the start of the assessment period in 1972 to the most recent assessment in 2014, for the base case model run. Years on the x-axis are fishing year with “1990” representing the 1989–90 fishing year. Years on the x-axis are fishing year with “2010” representing the 2009–10 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass is very unlikely to have been below 40% B_0 . Biomass is estimated to have been increasing or stable since 2003.
Recent Trend in Fishing Mortality or Proxy	Fishing pressure is estimated to have been generally declining since 1999.
Other Abundance Indices	–
Trends in Other Relevant Indicators or Variables	Recruitment since 1996 is estimated to have been fluctuating around or slightly below the long-term average for this stock.

Projections and Prognosis (2014)

Stock Projections or Prognosis	Biomass is uncertain but current catch is unlikely to cause decline. Catches at level of the TACC are likely to cause the stock to decline by about 10% in 5 years.
--------------------------------	---

Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Exceptionally Unlikely (< 1%) at current catch Hard Limit: Exceptionally Unlikely (< 1%) at current catch Soft Limit: Exceptionally Unlikely (< 1%) at TACC Hard Limit: Exceptionally Unlikely (< 1%) at TACC
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 – Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2014	Next assessment: 2019
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Summer research trawl survey series, annually since 1992 - Proportions-at-age data from the commercial fisheries and trawl survey - Line fishery CPUE series (annual indices since 1991): series not used in the base assessment model - Estimates of biological parameters (but note that M was estimated in the models) 	1 – High Quality 1 – High Quality 2 – Medium or Mixed Quality: likely change in q over time 1 – High Quality
Data not used (rank)	<i>Kaharoa</i> ECSI trawl survey abundance index	3– Low Quality: inadequate spatial coverage of the stock distribution
Changes to Model Structure and Assumptions	- No significant changes since the previous assessment	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Lack of contrast in survey indices - Uncertain catchability of trawl survey 	

Qualifying Comments
-

Fishery Interactions
Ling are often taken as a bycatch in hoki target trawl fisheries. Target line fisheries for ling have the main bycatch species of spiny dogfish, sea perch, sharks and skates, and ribaldo. Interactions with other species are currently being characterised.

- Sub-Antarctic (LIN 5 & 6, excluding the Bounty Plateau)

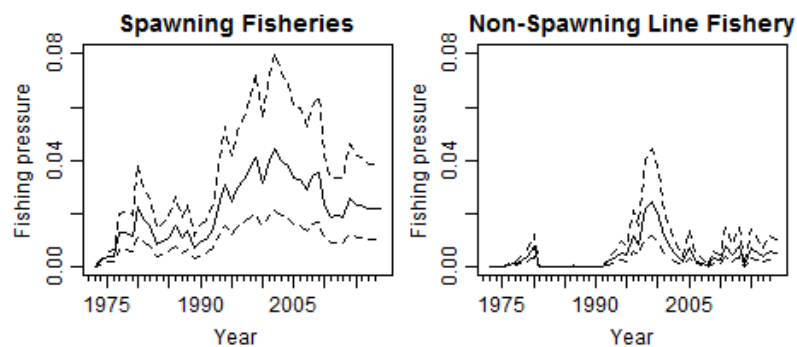

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	One base case
Reference Points	Management Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{40\%B_0}$
Status in relation to Target	B_{2018} was estimated to be between 75% and 101% B_0 ; Virtually Certain (> 99%) to be above the target
Status in relation to Limits	B_{2018} is Exceptionally Unlikely (< 1%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Overfishing is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the Sub-Antarctic ling stock from the start of the assessment period in 1972 to the most recent assessment in 2018, for the base case model run. Years on the x-axis are fishing year with “1990” representing the 1989–90 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass appears to have changed little in recent years.
Recent Trend in Fishing Mortality or Proxy	Fishing pressure is estimated to have been low, with little change.

LIN 5&6 base model: Exploitation rates (catch over vulnerable biomass) with 95% credible intervals shown as dashed lines.

Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	Stock status is unlikely to change over the next 5 years at recent catch levels or the level of the TACC (i.e., 12 100 t).
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Exceptionally Unlikely (< 1%) at current catch or catches at the level of the catch limit Hard Limit: Exceptionally Unlikely (< 1%) at current catch or TACC
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Exceptionally Unlikely (< 1%)

Assessment Methodology and Evaluation

Assessment Type	Level 1 – Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2018	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	

Main data inputs (rank)	<ul style="list-style-type: none"> - Summer and autumn <i>Tangaroa</i> trawl survey series - Proportions-at-age data from the commercial fisheries and trawl surveys - Estimates of biological parameters (but note that M was estimated in the models) 	1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	- Line fishery CPUE series (annual indices since 1991).	2 – Medium Quality: uncertainty in its ability to index abundance
Changes to Model Structure and Assumptions	<ul style="list-style-type: none"> - M was estimated as a constant - The annual cycle of the model and fishery catches were aligned - Free q's were used instead of nuisance q's 	
Major Sources of Uncertainty	- The lack of contrast in the summer trawl series (the main relative abundance series) makes it difficult to accurately estimate the upper bound of past and current biomass.	

Qualifying Comments

The current assessment assumes that LIN 5 and LIN 6 (except Bounty Islands LIN 6B) are a single biological stock.

Fishery Interactions

Ling are often taken as a bycatch in hoki target trawl fisheries. Target line fisheries for ling have the main bycatch species of spiny dogfish, sea perch, sharks and skates, and ribaldo. Interactions with other species are currently being characterised.

- **Bounty Plateau (part of LIN 6)**

Stock Status	
Year of Most Recent Assessment	2006
Assessment Runs Presented	A single model run
Reference Points	Management Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Not defined
Status in relation to Target	B_{2006} was estimated to be 61% B_0 ; Very Likely (> 90%) to be at or above the target
Status in relation to Limits	B_{2006} is Very Unlikely (< 10%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit.
Status in relation to Overfishing	-

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the Bounty Plateau ling stock from the start of the assessment period in 1980 to the most recent assessment in 2006. Years on the x-axis are fishing year with “1995” representing the 1994–95 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Median estimates of biomass are unlikely to have been below 61% B_0 . Biomass is estimated to have been declining since 1999.
Recent Trend in Fishing Mortality or Proxy	Fishing pressure is estimated to have been low, but erratic, since 1980.
Other Abundance Indices	–
Trends in Other Relevant Indicators or Variables	Recruitment was above average in the early 1990s, but below average in the late 1990s. No estimates of recruitment since 1999 are available.

Projections and Prognosis (2006)

Stock Projections or Prognosis	Stock status is predicted to continue declining slightly over the next 5 years at a catch level equivalent to the average since 1991 (i.e., 600 t per year).
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Note that there is no specific TACC for the Bounty Plateau stock. Soft Limit: Very Unlikely (< 10%) Hard Limit: Very Unlikely (< 10%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	-

Assessment Methodology and Evaluation

Assessment Type	Level 1 – Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2006	Next assessment: Unknown
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Proportions-at-age data from the commercial line fishery - Line fishery CPUE series (annual indices since 1992) - Estimates of biological parameters 	1 – High Quality 3 – Low Quality: fishery-dependent with possible changes in q over time 1 – High Quality
Data not used (rank)	N/A	

Changes to Model Structure and Assumptions	- No significant changes since the previous assessment
Major Sources of Uncertainty	- There are no fishery-independent indices of relative abundance, so the assessment is driven largely by the line fishery CPUE series. - Stock projections are based on a constant future catch of 600 t per year. However, historic catches from this fishery have fluctuated widely, so future catches could be markedly different from 600 t per year.
Qualifying Comments	
There is no separate TACC for this stock; it is part of the LIN 6 Fishstock that has a TACC of 8505 t.	

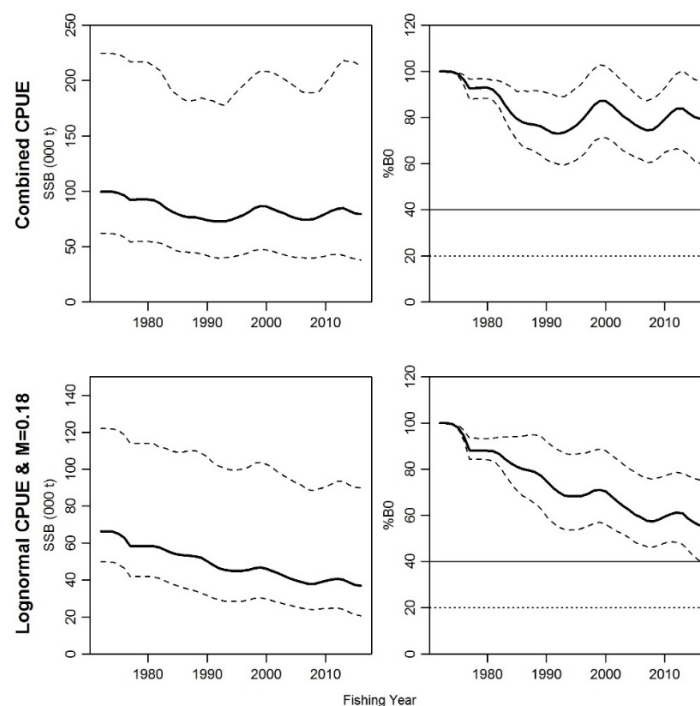

Fishery Interactions

Target line fisheries for ling have the main bycatch species of spiny dogfish, sharks and skates, and ribaldo. Interactions with other species are currently being characterised.

• West coast South Island (LIN 7)

Stock Status	
Year of Most Recent Assessment	2017
Assessment Runs Presented	Three alternative model runs
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $F_{40\%B_0}$
Status in relation to Target	B_{2017} was estimated to be about 79% B_0 , 66% B_0 , and 54% B_0 ; in all cases Very Likely (> 90%) to be at or above the target
Status in relation to Limits	B_{2017} is Exceptionally Unlikely (< 1%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Very Unlikely (< 10%)

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the most optimistic (Combined CPUE) and pessimistic (Lognormal CPUE & $M = 0.18$) model runs for the WCSI ling stock from the start of the assessment period in 1972 to the most recent assessment in 2017. Years on the x-axis are fishing year with “1990” representing the 1989–90 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass is estimated to have been stable or slowly decreasing.
Recent Trend in Fishing Intensity or Proxy	Stable (trawl and longline)
Other Abundance Indices	A CPUE index was available from the line (target) fishery but was not considered reliable. The time series of the inshore <i>Kaharoa</i> survey does not adequately cover the distribution of ling on the west coast.
Trends in Other Relevant Indicators or Variables	The age structures of both the commercial catch and trawl survey catch are broad, indicating a low exploitation rate.

Projections and Prognosis	
Stock Projections or Prognosis	Stock status is unlikely to change over the next 5 years at recent catch levels.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2017	Next assessment: 2020
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Catch history - Abundance index from WCSI trawl surveys - Abundance index from the commercial trawl hoki-hake-ling target fishery CPUE - Proportions at age data from the commercial fisheries and trawl surveys - Estimates of fixed biological parameters 	1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	<ul style="list-style-type: none"> - Commercial line fishery CPUE - <i>Kaharoa</i> trawl survey abundance index 	3 – Low Quality: does not track stock biomass 3 – Low Quality: inadequate spatial coverage of the stock distribution
Changes to Model Structure and Assumptions	- Reweighted sample sizes for age frequency data	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - There is a lack of contrast in the biomass indices to inform the absolute level of biomass. - Although the catch history used in the assessment has been corrected for some misreported catch (see Section 1.4), it is possible that additional misreporting exists. - It is assumed in the assessment models that natural mortality is constant over all ages. - The model estimates that a relatively high proportion of ling biomass is not vulnerable to fishing around the age of first maturity. 	

Qualifying Comments

This assessment is very uncertain but it is highly probable that B_{2017} is greater than 40% B_0 and it could be much higher.

Fishery Interactions

Ling are often taken as a bycatch in hoki target trawl fisheries. Target line fisheries for ling have the main bycatch species of spiny dogfish, sea perch, sharks and skates, and ribaldo. Interactions with other species are currently being characterised.

- Cook Strait (LIN 2 [Statistical Area 016] & part of LIN 7)

Stock Status

Year of Most Recent Assessment	2010 (an assessment in 2013 was rejected)
Assessment Runs Presented	A base case.
Reference Points	Target: 40% B_0 . Soft Limit: 20% B_0 . Hard Limit: 10% B_0 . Overfishing threshold: F corresponding to 40% B_0
Status in relation to Target	B_{2010} was estimated to be 54% B_0 ; Likely (> 60%) to be at or above the target.
Status in relation to Limits	B_{2010} is Exceptionally Unlikely (< 1%) to be below the Soft Limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit.
Status in relation to Overfishing	Overfishing is Very Unlikely (< 10%) to be occurring.

Historical Stock Status Trajectory and Current Status

Trajectory over time of spawning biomass (absolute, and % B_0 , with 95% credible intervals shown as broken lines) for the Cook Strait ling stock from the start of the assessment period in 1972 to the most recent assessment in 2010. Years on the x-axis are fishing year with “1990” representing the 1989–90 fishing year. Biomass estimates are based on MCMC results.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass is estimated to have been declining since 1999, but is unlikely to have dropped below 30% B_0 .
Recent Trend in Fishing Intensity or Proxy	Overall fishing pressure is estimated to have been relatively constant since the mid-1990s, but has trended down for trawl and up for line.
Other Abundance Indices	—
Trends in Other Relevant Indicators or Variables	Recruitment from 1995 to 2006 was low relative to the long-term average for this stock. There are no estimates for the more recent year classes.

Projections and Prognosis

Stock Projections or Prognosis	Stock status is predicted to improve slightly over the next 5 years at a catch level equivalent to that since 2006 (i.e., 220 t per year), or remain relatively constant at a catch equivalent to the mean since 1990 (i.e., 420 t per year).
--------------------------------	---

LING (LIN)

Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Note that there is no specific TACC for the Cook Strait stock. Soft Limit: Catch 220 t, Very Unlikely (< 10%); Catch 420 t, Very Unlikely (< 10%) Hard Limit: Catch 220 t, Exceptionally Unlikely (< 1%); Catch 420 t, Very Unlikely (< 10%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2010	Next assessment: 2020
Overall assessment quality rank	3 – Low Quality: The only accepted relative abundance series (trawl fishery CPUE) was not well fitted. A subsequent assessment in 2013 was rejected by the Working Group.	
Main data inputs (rank)	<ul style="list-style-type: none"> - Proportions-at-age data from the commercial trawl fishery - Proportions-at-age data from the commercial line fishery - Trawl fishery CPUE series (annual indices since 1994) - Estimates of biological parameters 	1 – High Quality 3 – Low Quality: not representative of entire fishery 2 – Medium or Mixed Quality: not well-fitted by model 1 – High Quality
Data not used (rank)	Line fishery CPUE	3 – Low quality: does not track stock biomass
Changes to Model Structure and Assumptions	No significant changes since the previous assessment.	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - There are no fishery-independent indices of relative abundance. It is not known if the trawl CPUE series is a reliable abundance index. - The stock structure of Cook Strait ling is uncertain. While ling in this area are almost certainly biologically distinct from the WCSI and Chatham Rise stocks, their association with ling off the lower east coast of the North Island is unknown. - It is possible that trawl selectivity has varied over time, resulting in poor fits to some age classes in some years. - Line fishery selectivity is based on only two years of catch-at-age data from the auto longline fishery. No information is available from the 'hand-baiting' line fishery. - The model is moderately sensitive to small changes in M, and M is poorly estimated. 	

Qualifying Comments
There is no separate TACC for this stock; it comprises parts of Fishstocks LIN 7 and LIN 2.

Fishery Interactions
Ling are often taken as a bycatch in hoki target trawl fisheries. Target line fisheries for ling have the main bycatch species of spiny dogfish, sea perch, sharks and skates. Interactions with other species are currently being characterised.

6. FUTURE RESEARCH

A review of the ling stock structure for LIN 2 should be completed before further assessments are conducted for this QMA.

LOOKDOWN DORY (LDO)*(Cyttus traversi)***1. FISHERY SUMMARY**

Lookdown dory was introduced into the Quota Management System (QMS) on 1 October 2004 with the allowances, TACs and TACCs in Table 1. It is currently managed as three stocks: LDO 1 which comprises FMAs 1–2 and 7–9; LDO 3 which comprises FMAs 3–6; and LDO 10 (Kermadec region).

Table 1: Recreational and customary non-commercial allowances, TACCs and TACs, by Fishstock, for lookdown dory.

Fishstock	Recreational Allowance	Customary non-commercial Allowance	TACC	TAC
LDO 1	0	0	168	168
LDO 3	0	0	614	614
LDO 10	0	0	1	1
Total	0	0	783	783

1.1 Commercial fisheries

Reliable landings data are available from 1989–90 onwards, after the introduction of Catch Landing Returns (CLRs) in the previous year (Table 2). Annual landings are also available from Licensed Fish Receiver Returns (LFRRs), and these agree well with CLR figures in most years (within 10%), but differ by 20–27% in 4 of the 12 years with comparable data (Table 3). Total landings (CLR) have increased steadily from 127 t in 1989–90 to 760 t in 2001–02. Estimated catch as a percentage of recorded landings were moderate in the early 1990s at 60–70%, but subsequently declined to around 30%. Lookdown dory will often not be included within the top five species in a trawl haul, but the reason for the declining percentage of landings recorded as catch is unknown.

Since entering the QMS, catches in LDO 1 have exceeded the TACC slightly in some years (Table 2). The TACC in LDO 3 has never been caught. This probably reflects the reduction in the size of the trawl fishery on the Chatham Rise where the greatest proportion of lookdown dory has been taken as bycatch. No catch has been reported from LDO 10. Figure 1 shows the historical landings and TACC values for LDO 1 and LDO 3.

There is a seasonal pattern of catch of lookdown dory on the west coast South Island in relation to target fishing for spawning hoki and hake in winter. Catches elsewhere are also dependent on fishing activity in target fisheries but, other than a slight decline in winter months in relation to the shift in area of operation of the hoki fleet, they tend to be less seasonal.

LOOKDOWN DORY (LDO)

Table 2: Reported domestic landings (t) of lockdown dory by Fishstock and TACC from 2004–05 to 2016–17.

-, data not available

Lookdown dory is generally caught by bottom trawling in depths of 200 to 800 m mainly as bycatch in the hoki fishery, but also in a variety of other target fisheries such as barracouta, hake, ling, scampi, squid and jack mackerel. A small amount of target fishing is reported from FMA 7. Most of the catch has come from FMA 3 (east coast South Island), FMA 4 (Chatham Rise), and FMA 7 (west coast South Island) (Table 4). Landings from around the North Island have been restricted mostly to a few tonnes each year from FMAs 1, 2, 8 and 9. In FMA 5 (Southland) and FMA 6 (Sub-Antarctic) landings have been in the order of 10-30 t over the past six years. 123 kg of lockdown dory were reported to have been caught from outside the New Zealand EEZ in the 2012–13 fishing year.

Table 4: Reported historic landings (rounded to nearest tonne) of lockdown dory by FMA and fishing year 1989–90 to 2003–04.

Year	FMA 1	FMA 2	FMA 3	FMA 4	FMA 5	FMA 6	FMA 7	FMA 8	FMA 9	FMA 10

1.2 Recreational fisheries

There is no quantitative information on recreational harvest levels of lockdown dory. Due to the offshore location and depth distribution of lockdown dory recreational catch is thought to be negligible.

Figure 1: Reported commercial landings and TACC for the two main LDO stocks. Left to right: LDO 1 (Challenger, Central, Auckland), and LDO 3 (South East Chatham Rise, South East Coast, Sub Antarctic, Southland). Note that this figure does not show data prior to entry into the QMS.

1.3 Customary non-commercial fisheries

An estimate of current catch is not available but given the offshore location and depth distribution of lockdown dory customary non-commercial catch is thought to be negligible.

1.4 Illegal catch

Estimates of illegal catch are not available.

1.5 Other sources of mortality

There is no quantitative information on the level of other sources of mortality.

2. BIOLOGY

Lookdown dory (*Cyttus traversi*) belongs to the family Zeidae. This family includes 13 species in seven genera distributed among the Atlantic and Pacific Oceans and the Mediterranean Sea. Lookdown dory also occurs in Australian waters, mostly east and south of Tasmania (where it is known as king dory), and also in South Africa. It is widely distributed throughout New Zealand waters with most records from the Chatham Rise. The geographical and depth distribution of immature (less than 33 cm) fish is similar to that of adults (Hurst et al 2000).

It is one of the less abundant members of a loosely associated group of about 23 common species, which together form the upper slope assemblage of New Zealand's continental shelf (Francis et al 2002). The main species in this group are hoki, javelin fish, ling, pale ghostshark, sea perch, hake, and

LOOKDOWN DORY (LDO)

longnose spookfish (chimaerid). It was identified as a key species characterising the demersal fish community 350–550 m on the Chatham Rise (Bull et al 2001).

Juveniles are found in surface waters up to a length of approximately 12 cm (May & Maxwell 1986), at which stage a metamorphosis occurs associated with the transition from a pelagic to a demersal habitat (James 1976). Adults are most common between 400 to 600 m, but have a wide depth range, from 50 to 1200 m (Anderson et al 1998). Immature fish less than 33 cm have a similar geographical and depth distribution to adults (Hurst et al 2000, O'Driscoll et al 2003). The main prey of lookdown dory are natant decapod crustaceans, followed by euphausiid, mysid, galatheid, and nephropsid crustaceans, and fish (Clark & King 1989, Forman & Dunn, 2010). Lookdown dory is likely to be prey of larger fish and have occasionally been recorded in the stomachs of large ling.

Trawl survey catch distribution across the Chatham Rise is fairly even, with females ranging from 10 to 55 cm total length, and males ranging from 10 to 45 cm. Lookdown dory show early signs of ripening to spawn in the January surveys (Livingston et al 2002). Catch distribution across the Sub-Antarctic is patchier than across the Chatham Rise, particularly during autumn surveys (O'Driscoll & Bagley 2001). Lookdown dory appear to grow larger in the Sub-Antarctic than on the Chatham Rise with females ranging from 12 to 60 cm total length, and males ranging from 12 to 45 cm.

There are no known aggregations or migrations associated with spawning lookdown dory. Around the North Island, female lookdown dory were reported to mature at about 35 cm (May & Maxwell 1986). Ripe specimens are usually seen in autumn and winter but have also been observed in summer (Clark & King 1989). Livingston et al (2002) reported early signs of ripening in January Chatham Rise trawl surveys. Observer records from the east coast South Island and Chatham Rise show that ripe females are more common in summer months and spent females are more common in winter (MacGibbon et al 2012). Females on the west coast South Island are mostly resting, immature or spent in winter. Although most spawning takes place in autumn and winter it is likely that it is not a discrete event but occurs over much of the year. Research data from other areas are sparse, but show the presence of fish in spawning condition in most months of the year.

Although there are no published studies of validated age and growth of lookdown dory, preliminary work in Australia suggests that this species may live to over 30 years (Stewart & Smith 1992). Tracey et al (2007) attempted to use lead-radium techniques to validate ageing by zone counts of otoliths but were unsuccessful. Based on unvalidated zone counts, they observed maximum ages of 38 and 25 years for males and females respectively for New Zealand lookdown dory from the Chatham Rise. Von Bertalanffy growth parameters are given in Table 5 and length-weight parameters are given in Table 6.

Table 5: Summary of von Bertalanffy growth parameters for Chatham Rise lookdown dory. Source : Tracey et al 2007. NB : Ageing in this study used unvalidated methods.

3. STOCKS AND AREAS

A catch-effort characterisation carried out in 2010 (MacGibbon et al 2012) identified three main fishing areas where lookdown dory are caught. These are the east coast South Island (FMA 3), Chatham Rise (FMA 4), and west coast South Island (FMA 7). It was found that these are still the main relevant fishing areas when this work was updated in 2012 (Ballara 2014).

There is little information on stock structure, recruitment patterns, or other biological characteristics on which to base any biological fishstock boundaries. MacGibbon et al (2012) found that both sexes grow to a larger size in the Sub-Antarctic compared with the Chatham Rise suggesting the possibility of different stocks. There is also a difference in abundance between males and females in both areas with females nearly always outnumbering males (Figure 2).

Figure 2: Doorspread biomass estimates of lookdown dory by sex from the Chatham Rise 1991 to 2014 (upper) and Sub-Antarctic 1991 to 1993 and 2000 to 2012 (lower), from *Tangaroa* surveys.

4. STOCK ASSESSMENT

In December 2013 the Middle Depths Working Group agreed that for the west coast South Island (FMA 7, which accounts for the vast majority of the LDO 1 catch), acceptable methods of monitoring abundance are relative biomass estimates from the west coast South Island winter trawl survey carried out by R.V. *Tangaroa*. Catch-per-unit-effort indices from daily processed commercial catches and from the scientific observer programme were also accepted as indices of abundance for the west coast of the South Island.

LOOKDOWN DORY (LDO)

The Middle Depths Working Group agreed in February 2011 that relative biomass estimates of lookdown dory from middle depth trawl surveys on the Chatham Rise and the Sub-Antarctic were suitable for monitoring major changes in lookdown dory abundance for LDO 3. Standardised CPUE indices from a mixed target species trawl fishery on the ECSI and Chatham Rise area were not accepted by the Working Group.

4.1 Estimates of fishery parameters and abundance

Lookdown dory biomass is usually in the top 10 species on the Chatham Rise and CVs are relatively precise (usually less than 15%) (Table 7). Females have consistently comprised more of the biomass than males (Figure 2). Biomass indices on the Sub-Antarctic have higher but still acceptable CVs (generally less than 30%). Relative biomass has been lower in the last two surveys. Biomass indices from the west coast South Island are considerably lower than those for the Chatham Rise and Sub-Antarctic but are still thought to be reliable measures of abundance.

Table 7: Biomass indices (t) and coefficients of variation (cv) for lookdown dory from *Tangaroa* trawl surveys (Assumptions: areal availability, vertical availability and vulnerability = 1). NB: estimates are for the core strata only for the respective time series.

Length frequency distributions of Chatham Rise lockdown dory suggest that recruitment is variable (MacGibbon et al, 2012, Ballara, 2014). Generally, when a strongly recruiting year class is present, the male length frequencies are often bimodal and females show two or three modes. Length frequency plots show that females are usually more numerous than males with a mean ratio for the time series of 1.15 females to every male (range 0.98–1.52). Males don't grow as large as females, with few males growing larger than 40 cm.

Length frequency distributions from the summer Sub-Antarctic series are less informative and no tracking of cohorts is possible. Overall, scaled population numbers are much lower for both sexes here than on the Chatham Rise but, again, females are more numerous than males with a mean ratio for the time series of 1.8 females for every male (range 0.55–3.9). Females also grow to a larger size than males and both sexes grow to a larger size on the Sub-Antarctic than on the Chatham Rise, which suggests that it may be a separate biological stock. This could also potentially be due to real differences in fishing pressure.

CPUE indices for lockdown dory on the WCSI were developed using the daily processed catch data and a smaller subset of observed vessels in the hoki and hake target fisheries. Both series show a similar trend, flat since 1995 (Figures 3 and 4).

Figure 3: Log normal CPUE indices for WCSI daily processed catch, bottom trawl target hoki or hake, showing catches (scaled to same mean as indices), and lognormal standardised and un-standardised indices. Bars indicate 95% confidence intervals. Year defined as June–September.

Figure 4: CPUE lognormal indices for WCSI observer programme data, target hoki or hake, bottom and midwater trawl, showing catches (scaled to same mean as indices), and lognormal standardised and un-standardised indices. Bars indicate 95% confidence intervals. Year defined as June–September.

LOOKDOWN DORY (LDO)

4.2 Yield estimates and projections

MCY cannot be estimated.

CAY cannot be estimated.

4.4 Other yield estimates and stock assessment results

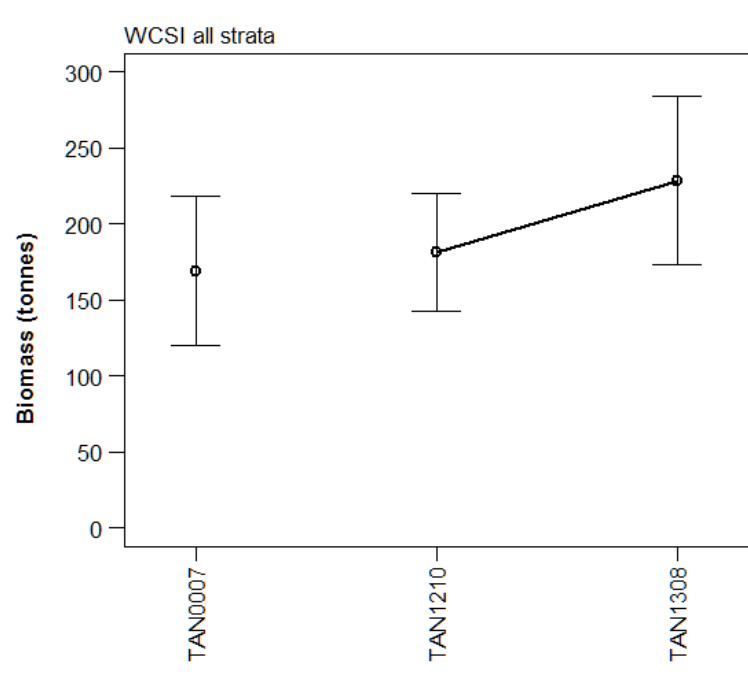

No information is available.

5. STATUS OF THE STOCK

There are no known sustainability concerns in the lockdown dory fishery. For LDO 1, the area which accounts for the vast majority of the lockdown dory catch is thought to be well monitored by trawl surveys which are currently too short to suggest any pattern, but CPUE indices suggest that abundance has been stable since the mid-1990s. For LDO 3, trawl surveys on the Chatham Rise and Sub-Antarctic indicate abundance has fluctuated in both areas

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Within LDO 1, FMA 7 biomass indices from the trawl survey time series are similar for 2000 and 2012, with an increase in 2013. This time series is only three points, but is thought to cover an appropriate depth and geographical range for lockdown dory. CPUE indices have been relatively flat since the mid-1990s.
Recent Trend in Fishing Mortality or Proxy	Unknown
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Stock size is unlikely (< 40%) to change much at current catch levels in FMA 7.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unlikely (< 40%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	-

Assessment Methodology		
Assessment Type	Level 2: Partial quantitative stock assessment	
Assessment Method	Evaluation of agreed CPUE indices and trawl survey indices thought to index abundance within FMA 7 of LDO 1. The vast majority of the LDO 1 catch is taken in FMA 7, catches in other areas of LDO 1 are minor.

Qualifying Comments

Fishery Interactions
In LDO 1, lockdown dory are taken primarily as bycatch in the bottom trawl west coast South Island hoki and hake target fisheries. Smaller catches are reported by midwater trawl. Interactions are the same as those for the hoki fishery. The east coast North Island scampi fishery also catches lockdown dory. A variety of other target fisheries also report catching lockdown dory but in very small amounts. A small amount of lockdown dory is targeted on the west coast of the South Island by smaller trawlers.

Historical Stock Status Trajectory and Current Status

Doorspread biomass estimates of lookdown dory (error bars are \pm two standard deviations) from the Chatham Rise, from *Tangaroa* surveys from 1991 to 2013.

Doorspread biomass estimates of lookdown dory (error bars are \pm two standard deviations) from the Sub-Antarctic, from *Tangaroa* surveys from 1991 to 1993, 2000 to 2009, and 2011–12.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy

Within LDO 3, FMAs 3 & 4 biomass indices have been fairly flat throughout the time series of Chatham Rise trawl surveys with the exception of 2010 and 2011 which show a decline. The 2012–14 surveys are more in line with previous years. For FMAs 5 & 6 biomass indices from the Sub-Antarctic series declined to 2002, steadily increased until 2009, and has dropped to the lowest estimates in the time series in 2011 and 2012.

Qualifying Comments
There is some indication that lockdown dory on the Chatham Rise may be a different stock to the Sub-Antarctic (i.e. different maximum sizes, evidence of some spawning activity in the Sub-Antarctic, as well as more extensively on the Chatham Rise)

Fishery Interactions
In LDO 3 lockdown dory are mainly caught as bycatch in the hoki target bottom trawl fishery but also in many other middle depth fisheries. Interactions are the same as those for the hoki fishery.

ORANGE ROUGHY (ORH)*(Hoplostethus atlanticus)***1. INTRODUCTION**

Orange roughy was introduced into the Quota Management System (QMS) on 1 October 1986. The main orange roughy fisheries have been treated separately for assessment and management purposes, and individual reports have been produced for each of six areas consisting of one or more stocks as follows:

1. Northern North Island (ORH 1)
 - Mercury-Colville stock
 - Other stocks
2. Cape Runaway to Banks Peninsula (ORH 2A, 2B, & 3A)
 - East Cape stock
 - Mid-East Coast stock
3. Chatham Rise and Puysegur (ORH 3B)
 - Northwest Chatham Rise stock
 - East and South Chatham Rise stock
 - Puysegur stock
 - Other minor stocks or subareas
4. Challenger Plateau (ORH 7A)
5. West coast South Island (ORH 7B)
6. Outside the EEZ
 - Lord Howe
 - Northwest Challenger
 - Louisville
 - West Norfolk
 - South Tasman

Recent orange roughy stock assessments have been conducted for Mid-East Coast, Northwest Chatham Rise, East and South Chatham Rise, and Challenger Plateau (2014), and Puysegur (2017). These assessments have used a similar approach and have relied on the use of ageing data and acoustic surveys of spawning plumes. The methods are described later in this introduction and a brief summary of the main results is also provided.

2. BIOLOGY

Orange roughy inhabit depths between 700 m and at least 1500 m within the New Zealand EEZ. They are most abundant between about 800 m and 1200 m. Their maximum depth range is unknown.

Orange roughy are slow-growing, long-lived fish. On the basis of otolith ring counts and radiometric isotope studies, orange roughy may live up to 120–130 years. Age determination from otolith rings has been validated by length-mode analysis for juveniles up to four years of age (Mace et al 1990), and adult ages have been validated using radiometric techniques in a study by Andrews & Tracey (2003).

Orange roughy otoliths have a marked transition zone in banding which is believed to be associated with the onset of maturity (Francis & Horn 1997). The estimates of transition-zone maturity range from 23 to 31.5 years for fish from various New Zealand fishing grounds (Horn et al 1998, Seafood Industry Council/NIWA unpublished data). However, spawning fish appear to be an older subset of the transition-zone mature fish as evidenced by the older ages and the larger sizes of fish caught on the spawning grounds. The age at which 50% of fish are spawning was estimated in the 2014 stock assessment models to range from 32–41 years (see Section 4.2). Orange roughy in New Zealand waters reach a maximum size of about 50 cm standard length (SL), and 3.6 kg in weight, but the maximum size appears to vary among local populations. Average size is around 35 cm SL, although there is variation between areas.

Spawning occurs once each year between June and early August in several areas within the New Zealand EEZ, from the Bay of Plenty in the north, to the Auckland Islands in the south. Spawning occurs in dense aggregations at depths of 700–1000 m and is often associated with bottom features such as pinnacles and canyons. Spawning fish are also found outside the EEZ on the Challenger Plateau, Lord Howe Rise, and Norfolk Ridge to the west, and the Louisville Ridge to the east.

Fecundity is relatively low, with females carrying on average about 40 000–60 000 eggs. The eggs are large (2–3 mm in diameter), are fertilised in the water column, and then drift upwards towards the surface and remain planktonic until they hatch close to the bottom after about 10 days. Details of larval biology are poorly known.

Orange roughy juveniles are first available to bottom trawls at age about 6 months, when they exhibit a mean length of about 2 cm. Juveniles have been found in large numbers in only one area, at a depth of 800–900 m about 150 km east of the main spawning ground on the north Chatham Rise.

Orange roughy also form aggregations outside the spawning period, presumably for feeding. Their main prey species include mesopelagic and benthopelagic prawns, fish and squid, with other organisms such as mysids, amphipods and euphausiids occasionally being important.

Natural mortality (M) has been estimated to be 0.045 yr^{-1} . This was based on otolith age data from a 1984 research survey of the Chatham Rise that used an estimation technique based on mean age. A similar estimate was obtained in 1998 from a lightly fished population in the Bay of Plenty.

Biological parameters used in the following assessments (Tables 1 and 2) were estimated by Doonan (1994) with modifications of A_r , A_m , S_r , and S_m for the 1998 stock assessment meetings by Francis & Horn (1997), Horn et al (1998), and Doonan et al (1998), and further modifications for the 2006 assessment by Hicks (2006).

Biases in reading ages from otoliths were identified, leading to a recommendation by reviewers of orange roughy workshops in October 2005 and February 2006 that no age data should be used in assessments until the biases were quantified and corrected. Stemming from this recommendation, a new ageing methodology was developed for orange roughy in 2007, associated with an international ageing workshop for this species (Tracey et al 2007). In the 2014 stock assessments, age-frequency data were only used if the otoliths had been read using the new ageing protocol.

It is believed that ages derived from otoliths collected during the 1984 and 1990 trawl surveys of the

East Chatham Rise, which were aged under the old NIWA protocol do not contain serious biases. The single-sex growth curve, the length-weight parameters and the maturity ogive based on transition zones, which are all based on ageing using the old-protocol data are still believed to be valid. The estimates of these biological parameters (Table 1) were used for both the East Chatham Rise and the Northwest Chatham Rise stock assessments, although the otoliths used were collected from the East Chatham Rise only (of which most were from the Spawning Box). The transition-zone maturity estimates were not used in the 2014 stock assessments as maturity was estimated in each of the models.

Table 1: Biological parameters as used for orange roughy assessments. -, not estimated.

Puysegur Bank	-	-	27	-	-	3
Bay of Plenty	26	27	-	4	5	-

The method of Francis (1992) was used to estimate reference points and yields for orange roughy stocks. The differing parameter values in Tables 1 and 2 by stock meant that yield estimates varied across stocks (Table 3).

Table 3: Estimates of MCY , E_{CAY} and MAY for New Zealand orange roughy.

Area	MCY (% B_0)	E_{CAY}	MAY (% B_0)
Bay of Plenty (ORH 1)	1.47	0.063	1.94
Ritchie Bank (ORH 2A)	1.46	0.062	1.92
Chatham Rise (ORH 3B)	1.51	0.064	1.99
Puysegur Bank (ORH 3B)	1.47	0.062	1.94
Challenger Plateau (ORH 7A)	1.40	0.060	1.84

For all these stocks, the mean biomass when fishing using an MCY policy was estimated to be 51% of

ORANGE ROUGHY (ORH)

B_0 , and for a CAY policy it was 30% of B_0 (these values varied by less than 1% between the various stocks).

The reference points and yields given above are not used in the 2014 stock assessments. In these assessments, MCMC estimates of deterministic reference points and yields were made for the target biomass range of 30–40% B_0 . However, the lower bound of this range was taken from the above results (the mean biomass under a CAY policy).

3. ENVIRONMENTAL AND ECOSYSTEM CONSIDERATIONS

This section was updated for the 2018 Fishery Assessment Plenary. This summary is from the perspective of the deepwater trawl fisheries for orange roughy; an issue-by-issue analysis is available in the 2017 Aquatic Environment & Biodiversity Annual Review (MPI 2017,

<https://www.mpi.govt.nz/dmsdocument/27471-aquatic-environment-and-biodiversity-annual-review-aebur-2017-a-summary-of-environmental-interactions-between-the-seafood-sector-and-the-aquatic-environment>).

3.1 Role in the ecosystem

Orange roughy are the dominant demersal fish at depths of 750–1100 m on the north and east Chatham Rise, the east coast of the North Island south of about East Cape, and the Challenger Plateau (Clark et al 2000; Doonan & Dunn 2011; Tracey et al 1990). An analysis of New Zealand demersal fish assemblages using research trawl data showed that orange roughy was the most frequently occurring species (found in more than 40 % of tows) in the mid slope assemblage (Francis et al 2002). Fishing has reduced the abundance of orange roughy since the 1980s, and the effects of removing, for example, an average of about 18 000 t per year from ORH 3B between 1979–80 and 2009–10 are largely unknown. There are likely to have been ecosystem implications (Tracey et al 2012).

3.1.1 Trophic interactions

The main prey species of orange roughy include mesopelagic and benthopelagic prawns, fish and squid, with other organisms such as mysids, amphipods and euphausiids occasionally being important (Rosecchi et al 1988). Koslow (1997) showed that orange roughy have a faster metabolism than deepwater fishes that are typically dispersed over the flat seafloor, and their food consumption is higher. Ontogenetic shifts occur in their feeding preferences with the smaller fish (up to 20 cm) feeding on crustaceans, and larger fish (31 cm and above) feeding on teleosts and cephalopods (Stevens et al 2011). Relative proportions of the three prey groups were similar between areas. Bulman & Koslow (1992) found that teleosts were more important than crustaceans by weight in the prey of Australian orange roughy, and that this dominance increased in adult-sized fish. Dunn & Forman (2011) inferred from diet analysis that juveniles feed more on the benthos compared with the benthopelagic foraging of adults. Where they co-occur, orange roughy and black oreo may compete for teleost and crustacean prey.

Predators of orange roughy are likely to change with fish size. Larger smooth oreo, black oreo and orange roughy were observed with healed soft flesh wounds, typically in the dorso-posterior region. Wound shape and size suggest they may be caused by one of the deepwater dogfishes (Dunn et al 2010). Giant squid and sperm whales have also been found to prey on orange roughy (Gaskin & Cawthorn 1967, Jereb & Roper 2010).

3.1.2 Ecosystem Indicators

Tuck et al (2009) used data from the Sub-Antarctic and Chatham Rise middle-depth trawl surveys to derive indicators of fish diversity, size, and trophic level. However, fishing for orange roughy occurs mostly deeper than the depth range of these surveys and is only a small component of fishing in the areas considered by Tuck et al (2009).

3.2 Bycatch (fish and invertebrates)

Anderson (2011) summarised the bycatch of orange roughy and oreo trawl fisheries from 1990–91 to 2008–09. For orange roughy trawls since 2005–06, orange roughy accounted for about 84% of the total

observed catch and the remainder comprised mainly oreos (10%), hoki (0.4%), and cardinalfish (0.3%). About 240 other species or species groups were recorded by observers, including various deepwater dogfishes (1.8%), rattails (1.0%), morid cods (0.8%), and slickheads (0.3%). Total annual bycatch in the orange roughy fishery has been as high as 27 000 t but has declined with the TACC and was less than 4 000 t between 2005–06 and 2008–09 (non-commercial species comprising only 5–10% of the total). Total annual discards also decreased over time, from about 3400 t in 1990–91 to about 300 t in 2007–08 and, since about 2000, has been almost entirely of non-QMS species (rattails, shovelnose spiny dogfish, and other deepwater dogfishes).

Invertebrate species are caught in low numbers in the orange roughy fishery (Anderson 2011). Squid (mostly warty squid, *Moroteuthis* spp.) were the largest component of invertebrate catch, followed by various groups of coral, echinoderms (mainly starfish), and crustaceans (mainly king crabs, family Lithodidae). Tracey et al (2011) analysed the distribution of nine groups of protected corals based on bycatch records from observed trawl effort from 2007–08 to 2009–10, primarily from 800–1000 m depth. For the orange roughy target fishery, about 10% of observed tows in FMAs 4 and 6 included coral bycatch, but a higher proportion of tows in northern waters included coral (28% in FMA 1, 53% in FMA 9, Tracey et al 2011).

3.3 Incidental Capture of Protected Species (seabirds, mammals, and protected fish)

For protected species, capture estimates presented here include all animals recovered to the deck (alive, injured or dead) of fishing vessels but do not include any cryptic mortality (e.g., seabirds struck by a warp but not brought onboard the vessel, Middleton & Abraham 2007, Brothers et al 2010).

3.3.1 Marine mammal interactions

Trawlers targeting orange roughy, oreo, and black cardinalfish occasionally catch New Zealand fur seal (which were classified as “Not Threatened” under the NZ Threat Classification System in 2010, Baker et al 2016). Between 2002–03 and 2007–08, there were 14 observed captures of NZ fur seal in orange roughy, oreo, and black cardinalfish trawl fisheries. There has been one observed capture in the period between 2008–09 and 2016–17, during which time the average level of annual observer coverage was 26.7% (Table 4). Corresponding mean annual estimated captures in this period ranged 0–3 (mean 1.25) based on statistical capture models (Thompson et al 2013; Abraham et al 2016). All observed fur seal captures occurred in the Sub-Antarctic region.

Table 4: Number of tows by fishing year and observed and model-estimated total NZ fur seal captures in orange roughy, oreo, and cardinalfish trawl fisheries, 2002–03 to 2016–17. No. Obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows, % inc, percentage of total effort included in the statistical model. Estimates are based on methods described in Abraham et al (2016), available via <https://data.dragonfly.co.nz/psc>. Estimates from 2002–03 to 2015–16 are based on data version 2017v1.

3.3.2 Seabird interactions

Annual observed seabird capture rates in the orange roughy, oreo and cardinalfish trawl fisheries have ranged from 0 to 0.9 per 100 tows between 2002–03 and 2016–17 (Table 5). The average capture rate in deepwater trawl fisheries (including orange roughy, oreo and cardinalfish) for the period from 2002–03 to 2016–17 is about 0.29 birds per 100 tows, a very low rate relative to other New Zealand trawl fisheries, e.g. for scampi (4.43 birds per 100 tows) and squid (13.79 birds per 100 tows) over the same years.

Table 5: Number of tows by fishing year and observed seabird captures in orange roughy, oreo, and cardinalfish trawl fisheries, 2002–03 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows. Estimates are based on methods described in Abraham et al (2016) and Abraham & Richard (2017, 2018) and available via <http://www.fish.govt.nz/en/nz/Environmental/Seabirds/>. Estimates from 2002–03 to 2015–16 are based on data version 2017v1.

	Fishing effort			Observed captures		Estimated captures	
	Tows	No. obs	% obs	Captures	Rate	Mean	95% c.i.

2016–17	3 971	1 226	30.9	2	0.2		

Salvin's albatross was the most frequently captured albatross (50% of observed albatross captures) but seven other albatross species have been observed captured since 2002–03. Cape petrels were the most frequently captured other taxon (36% of other taxon observed caught not including albatross species, Table 6). Seabird captures in the orange roughy, oreo, and cardinalfish fisheries have been observed mostly around the Chatham Rise and off the east coast South Island. These numbers should be regarded as only a general guide on the distribution of captures because the observer coverage is not uniform across areas and may not be representative.

Table 6: Number of observed seabird captures in orange roughy, oreo, and cardinalfish fisheries, 2002–03 to 2016–17, by species and area. The risk category is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the Population Sustainability Thresholds, PST (from Richard & Abraham 2015 where full details of the risk assessment approach can be found). It is not an estimate of the risk posed by fishing for cardinal fish. These data are available via <https://data.dragonfly.co.nz/psc>, based on data version 2017v1.

Species	Risk Category	Chatham Rise	East Coast South Island	Fiordland	Sub-Antarctic	Stewart Snare Shelf	West Coast South Island	Total

The deepwater trawl fisheries (including the cardinal fish target fishery) contributes to the total risk posed by New Zealand commercial fishing to seabirds (see Table 7). The two species to which the fishery poses the most risk are Chatham Island albatross and Salvin's albatross, with this suite of fisheries posing 0.06 and 0.022 of Population Sustainability Threshold (PST) (Table 7). Chatham albatross and Salvin's albatross were assessed at high risk (Richard et al 2017).

Table 7: Risk ratio of seabirds predicted by the level two risk assessment for the orange roughy and all fisheries included in the level two risk assessment, 2006–07 to 2016–17, showing seabird species with a risk ratio of at least 0.001 of PST (from Richard et al 2017 where full details of the risk assessment approach can be found). The risk ratio is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the PBR. The DOC threat classifications are shown (Robertson et al 2017 at <http://www.doc.govt.nz/documents/science-and-technical/nztes19entire.pdf>).

Species name	PST (mean)	Risk ratio			DOC Threat Classification
		ORH, OEO, CDL target trawl	TOTAL	Risk category	
Chatham Island albatross	425.2	0.060	0.362	High	At Risk: Naturally Uncommon

White-headed petrel	34 314.8	0.000	0.001	Negligible	Not Threatened

Mitigation methods such as streamer (tori) lines, Brady bird bafflers, warp deflectors, and offal management are used in the orange roughy, oreo, and cardinalfish trawl fisheries. Warp mitigation was voluntarily introduced from about 2004 and made mandatory in April 2006 (Department of Internal Affairs 2006). The 2006 notice mandated that all trawlers over 28 m in length use a seabird scaring device while trawling (being “paired streamer lines”, “bird baffle” or “warp deflector” as defined in the notice).

3.4 Benthic interactions

Orange roughy, oreo, and cardinalfish are taken using bottom trawls and accounted for about 14% of all tows reported on TCEPR forms to have been fished on close to the bottom between 1989–90 and 2004–05 (Baird et al 2011). Black et al (2013) estimated that, between 2006–07 and 2010–11, 98% of

orange roughy catch was reported on TCEPR forms. Tows are located in Benthic Optimised Marine Environment Classification (BOMEC, Leathwick et al 2009) classes J, K (mid-slope), M (mid-lower slope), N, and O (lower slope and deeper waters) (Baird & Wood 2012), and 94% were between 700 and 1 200 m depth (Baird et al 2011). Deepsea corals in the New Zealand region are abundant and diverse and, because of their fragility, are at risk from anthropogenic activities such as bottom trawling (Clark & O'Driscoll 2003, Clark & Rowden 2009, Williams et al 2010). All deepwater hard corals are protected under Schedule 7A of the Wildlife Act 1953. Baird et al (2012) mapped the likely coral distributions using predictive models, and concluded that the fisheries that pose the most risk to protected corals are these deepwater trawl fisheries.

Trawling for orange roughy, like trawling for other species, is likely to have effects on benthic community structure and function (e.g., Rice 2006) and there may be consequences for benthic productivity (e.g., Jennings et al 2001, Hermsen et al 2003, Hiddink et al 2006, Reiss et al 2009). These consequences are not considered in detail here but are discussed in the Aquatic Environment and Biodiversity Annual Review 2013 (MPI, 2013).

The NZ EEZ contains 17 Benthic Protection Areas (BPAs) that are closed to bottom trawl fishing and include about 52% of all seamounts over 1500 m elevation and 88% of identified hydrothermal vents.

3.5 Other considerations

Fishing during spawning may disrupt spawning activity or success. Morgan et al (1999) concluded that Atlantic cod (*Gadus morhua*) “exposed to a chronic stressor are able to spawn successfully, but there appears to be a negative impact of this stress on their reproductive output, particularly through the production of abnormal larvae”. Morgan et al (1999) also reported that “Following passage of the trawl, a 300-m-wide “hole” in the [cod spawning] aggregation spanned the trawl track. Disturbance was detected for 77 min after passage of the trawl.” There is no research on the disruption of spawning orange roughy by fishing in New Zealand.

3.5.2 Genetic effects

Fishing, environmental changes, including those caused by climate change or pollution, could alter the genetic composition or diversity of a species. There are no known studies of the genetic diversity of orange roughy from New Zealand. Genetic studies for stock discrimination are reported under “stocks and areas”.

3.5.3 Habitat of particular significance to fisheries management

Habitat of particular significance for fisheries management (HPSFM) does not have a policy definition (MPI, 2013). Mace et al (1990) identified only one area of high abundance for juvenile orange roughy at 800–900 m depth about 150 km east of the main spawning ground on the north Chatham Rise. Orange roughy from 9 cm SL have also been located on the Challenger Plateau and O'Driscoll et al (2003) show other areas where immature fish are relatively common. Dunn et al (2009) showed that orange roughy juveniles are generally found close to the seabed, and in shallower water than the adults, starting off at depths of around 850–900 m and spreading deeper, and over a wider depth range, as they grow. Dunn & Forman (2011) also suggested that juveniles start on flat grounds shallower than the adults, that they shift deeper as they grow, and that seamounts and other features tend to be dominated by the largest orange roughy. It is not known if there are any direct linkages between the congregation of orange roughy around features and the corals found on those features. Bottom trawling for orange roughy has the potential to affect features of the habitat that could qualify as habitat of particular significance to fisheries management.

4. RECENT STOCK ASSESSMENTS¹

Stock assessments were undertaken for ORH 7A areas in 2014, for Puysegur in 2017, and the Mid-east coast (MEC), Northwest Chatham Rise (NWCR), and East and South Chatham Rise (ESCR) in 2018. In this section, the methods that were common to these stock assessments are described and the main results are summarised.

4.1 Methods

The methods used in recent orange roughy assessments from 2014 were different from those used in previous years. The major differences were in the application of a more stringent data quality threshold, in model structure, and in the use of age data to estimate year class strengths.

4.1.1 Data quality and model structure

A high quality threshold was imposed on data before they were used in an assessment. This resulted in the exclusion of biomass estimates that had previously been used. In particular, CPUE indices were not used in any of the assessments because they were considered unlikely to be monitoring stock-wide abundance (e.g., non-spawning season catch rates from a single hill feature or complex within a large area cannot be monitoring stock wide abundance as the fishery would not have been sampling a large proportion of the stock; at best, such CPUE indices may index localised abundance; during the spawning season catches from a single hill or aggregation may be sampling a large proportion of the stock but the catch rates will depend on how the aggregation is fished rather than how much biomass is present). Also, estimates of biomass from egg surveys were not used as it was found that the available estimates were from surveys where the assumptions of the survey design were not met and/or there were major difficulties in analysing the survey data. Finally, acoustic-survey estimates of biomass were only used when mainly single-species aggregations were surveyed with suitable equipment. Estimates of spawning orange roughy biomass were accepted for plumes on the flat surveyed using hull-mounted transducers or towed systems, or for plumes on underwater features using towed systems only (otherwise the dead zone can be too large for reliable comparison).

The model structure assumed was similar across the assessments. In each case, the base models were single-sex, single-area models with separate categories for age and maturity. Maturity was estimated within the model from age-frequencies of spawning fish and, if available, from female proportion spawning at age data from pre-spawning wide-area trawl surveys (available for NWCR and MEC). All mature fish were assumed to spawn each year as this was consistent with the estimates of female proportion spawning at age (see the NWCR and MEC assessments). This is different to earlier assessments where acoustic and egg survey estimates of spawning biomass were scaled up using estimates of transition-zone mature biomass before being used in an assessment. In the recent assessments, acoustic estimates of *spawning* biomass were used directly without scaling.

The recent assessment models now include more reliable age data using the new ageing methodology (Tracey et al 2007, Horn et al 2016). Previously, the stock assessments were not thought to be reliable as the models were found to be insensitive to the recent abundance data; i.e., results did not change whether or not recent abundance indices were included because the model assumptions - particularly the assumption of deterministic recruitment - overwhelmed the data. The modelled biomass trajectories were estimated as a strong increasing trend as catches were scaled back, a pattern that was not supported by the fishery-independent abundance indices.

4.1.2 Acoustic q priors

The major sources of recent abundance information in the models are from acoustic surveys of spawning biomass. For each survey, the spawning biomass estimate was included in the appropriate assessment

¹ The information presented reflects the management settings that were in place since 2014 which guided the projections and advice provided. The management settings were updated in August 2014 and the management target range and a harvest control rule have been implemented for key orange roughy fisheries (ORH 3B Northwest Rise, ORH 3B East & South Rise, ORH 7A). The change does not change the status of the stocks in relation to reference points but it has led to a reduction in yield estimates. For more information on current management settings, please see Cordue, 2014. (<http://deepwater.co.nz/wp-content/uploads/2014/08/Cordue-2014-A-Management-Strategy-Evaluation-for-Orange-Roughy-ISL-Re....pdf>)

as an estimate of *relative* spawning biomass rather than *absolute* spawning biomass (the latter being used in previous assessments). The reason that the estimates are not used as absolute estimates of biomass is because there are two major potential sources of bias: (i) the estimates may be biased low or high because the estimate of orange roughy target strength is incorrect, and (ii) the survey is unlikely to have covered all of the spawning stock biomass. The unknown proportionality constant, or q , for each survey was estimated in the model using an informed prior for each q . Each prior was constructed from two components: orange roughy target strength and availability to the survey.

The target strength (TS) prior was derived from the estimates of Macaulay et al (2013) and Kloser et al (2013) who both obtained TS estimates (at 38 kHz) from visually verified orange roughy as they were herded by a trawl net (the “AOS” was mounted on the head of the net and acoustic echoes and stereo photos were obtained simultaneously). Macaulay et al (2013) estimated a TS (for 33.9 cm fish) of -52.0 dB with a 95% CI of -53.3 to -50.9 dB; Kloser et al (2013) gave a point estimate of -51.1 dB and gave a range, that allowed for the artificial tilt angles of the herded fish, from -52.2 to -50.7 dB. The prior was taken to be normal with a mean of -52.0 dB with 99% of the distribution covered by ± 1.5 dB (which covers both ranges). This results in a tight distribution for informed acoustic q priors, reflecting the high confidence in the target strength estimates.

For surveys that covered “most” of the spawning stock biomass (e.g., ESCR where in some years surveys covered the Old plume², the Rekohu plume, and the “Crack”), availability was modelled with a Beta(8,2) distribution (this has a mean of 0.8 – i.e., it is assumed *a priori* that 80% of the spawning stock biomass is being indexed). The acoustic q prior is the combination of the availability and TS priors (assuming they are independent). This was approximately normal with a mean of 0.8 and a CV of 19%. For surveys that were considered to have covered less than “most” of the spawning biomass, a similar prior was used for the q except that a lower mean value was assumed for the “availability” component of the prior (see individual assessments for how the mean was derived in these cases). When a higher CV was applied, the median estimates of biomass and stock status were slightly higher, and the confidence intervals were wider with a much higher upper bound.

4.1.3 Year class strength estimation

The number of year class strengths (YCSs) estimated within each model depended on the timing and number of age frequency observations available. In general a YCS was estimated provided that it was observed in at least one age frequency when it was neither “too old” nor “too young”. “Old” YCSs were not estimated because it was considered that there was too little information about these cohorts as only a few of them remained. “Too young” YCSs were not estimated because the selectivity for these ages is low and consequently the YCS estimates would be unreliable.

The Haist parameterisation for estimating YCS was used for all models (Bull et al 2012). In the 2013 MEC assessment it was found that the alternative Francis parameterisation unduly restricted YCS estimates as evidenced by poor fits to the trawl survey biomass indices. In contrast, the Haist parameterisation, using uniform priors, resulted in a good fit to the abundance indices at the MPD stage and an adequate fit at the MCMC stage. The YCS estimates were primarily driven by the composition data (age and length frequencies), but if unduly penalised, the estimates are restricted to a space which does not allow the trawl biomass indices to be fitted well. In the recent assessments a “nearly uniform” prior was used with the Haist parameterisation (lognormal with mode = 1, and log-space s.d. = 4).

4.1.4 Model runs

For each assessment, a similar set of sensitivity runs was conducted. In addition to a base model, there were runs that estimated natural mortality (M); halved and doubled the recent acoustic biomass estimates (to show that the model was sensitive to recent biomass indices); assumed deterministic recruitment (to show the impact of estimating year class strengths); increased/decreased the mean of acoustic q priors; and two sensitivities that simultaneously increased/decreased M and decreased/increased the mean of the acoustic q priors by 20% (a lower stock status occurs when M is decreased and when the mean of the acoustic q priors is increased; similarly an increased stock status occurs for changes in the other direction). The runs estimating M (“EstM”) and those with the 20%

²For clarity, what was previously described as the ‘Spawning plume’ located in the Spawning Box has been renamed the ‘Old-plume’ so as to differentiate it from the Rekohu plume, which is also a spawning plume.

changes in M and the mean of acoustic q priors (“LowM-Highq” and “HighM-Lowq”) were taken through to MCMC.

4.1.5 Fishing intensity

Fishing intensity for each year of the assessment was measured in units of 100 – ESD (Equilibrium Stock Depletion). This quantity was estimated by running the model to deterministic equilibrium, given the exploitation rate and fishing pattern associated with each year. The equilibrium level of the spawning biomass will be the ESD for that year (e.g., if the stock is fished at a very high fishing intensity, the equilibrium spawning stock biomass will be close to zero: $ESD = 0\% B_0$; if the stock is being very lightly fished, then $ESD = 100\% B_0$). The quantity $(100 - ESD)$ ranges from 0–100 with 100 denoting any pattern and level of fishing that would eventually reduce the stock down to zero spawning biomass. In general, the fishing intensity associated with a deterministic equilibrium of $x\% B_0$ is denoted as $U_{x\%B_0}$. To aid with the interpretation of fishing intensity in both the fishing intensity and “snail trail” plots (which have fishing intensity on the right hand y-axis), the value $U_{x\%B_0}$ has been replaced with an associated exploitation rate proxy on the left hand y-axis. Exploitation rate, expressed as a percentage, is the number of fish caught from every 100 available fish. The exploitation rate labels represent a median exploitation rate, as each $U_{x\%B_0}$ maps to a range of exploitation rates, rather than to a single number.

4.1.6 Projections

Projections were generally conducted over a 5-year time period at the level of the current catch and at the long-term yield associated with $U_{35\%B_0}$ (the fishing intensity associated with the mid-point of the target biomass range of 30–40% B_0). In each case, the future YCSs were assumed for immediately after the last estimated YCS and were resampled from the last 10 years of estimates (this is done because YCSs are correlated rather than being independent from year to year). For long-term projections (e.g., for MEC to estimate T_{min} , the number of years required for the stock to be rebuilt when there is no fishing), the YCSs were resampled from all estimated YCSs to ensure that the resampled YCSs will average to near 1 (so that there is no implied regime shift). Projections were done for the base model and, as a “worse-case scenario”, for the *LowM-Highq* model.

5. FUTURE RESEARCH

More age information is needed for all stocks. For most areas, this may simply necessitate reading otoliths that have previously been collected. Increasing the number of years with age-composition data should enable better estimation of year class strengths, and should increase the number of YCSs able to be estimated.

For those stocks where the proportion spawning at age is used (e.g. MEC), investigate alternatives for estimating the proportion spawning at age given the sparse data; for example, consider making it asymptotic at a younger age.

The design and implementation of the Challenger (ORH 7A) combined trawl and acoustic survey needs to be reviewed to ensure that it is fit for purpose for future years.

ORANGE ROUGHY NORTHERN NORTH ISLAND (ORH 1)

1. FISHERY SUMMARY

1.1 Commercial fisheries

This region extends northwards from west of Wellington around to Cape Runaway. Prior to 1993–94 there was no established fishery, and reported landings were generally small (Table 1). A new fishery developed in winter 1994, when aggregations were fished on two hill complexes in the western Bay of Plenty. In 1996 catches were also taken off the west coast of Northland. Figure 1 shows the historical landings and TACC values for ORH 1.

A TACC of 190 t was set from 1989–90. Prior to that there had been a 10 t TAC and various levels of exploratory quota. From 1995–96, ORH 1 became subject to a five year adaptive management programme, and the TACC was increased to 1190 t. A catch limit of 1000 t was applied to an area in the western Bay of Plenty (Mercury-Colville ‘box’), with the former 190 t TACC applicable to the remainder of ORH 1. In 1994 and 1995, research fishing was also carried out under Special Permit (not included in the TACC). For the period June 1996–June 1997, a Special Permit was approved for exploratory fishing. This allowed an additional 800 t (not included in the TACC) to be taken in designated areas, although catches were limited from individual features (hills and seamounts etc).

Table 1: Reported landings (t) and TACCs (t) from 1982–83 to present. - no TACC. The reported landings do not include catches taken under an exploratory special permit of 699 t in 1998–99 and 704 t in 1999–2000. QMS data from 1986-present.

Fishing year	Reported landings			
	West coast	North-east coast	Total	TACC
1982–83*	< 0.1	0	< 0.1	-

* FSU data.

+ Unknown distribution of catch.

Reported catches have varied considerably between years, and the location of the catch in the late 1980s/early 1990s is uncertain, as some may have been taken from outside the EEZ, as well as

ORANGE ROUGHY (ORH 1)

misreported from other areas. Research fishing carried out under Special Permit in 1994 and 1995 resulted in catches of 45.2 t and 200.7 t, respectively (not included in Table 1).

Based on an evaluation of the results of an Adaptive Management Programme (AMP) for the Mercury-Colville box initiated in 1995, the AMP was concluded and the TACC was reduced to 800 t for the 2000–01 fishing year. Catch limits of 200 t were established in each of four areas in ORH 1, with an individual seamount feature limit of 100 t. From 1 October 2001, ORH 1 was reintroduced into the AMP with different design parameters for the five years, and the TACC was increased from 800 to 1400 t and allocated an allowance of 70 t for other mortality caused by fishing. The AMP was discontinued in 2007.

In recent years the fishery has also developed off the west coast and sizeable catches have been taken off the Tauroa Knoll and West Norfolk Ridge.

Figure 1: Reported commercial landings and TACC for ORH 1 (Auckland).

1.2 Recreational fisheries

There is no known non-commercial fishery for orange roughy in this area.

1.3 Customary non-commercial fisheries

No customary non-commercial fishing for orange roughy is known in this area.

1.4 Illegal catch

No quantitative information is available on the level of illegal catch in this area.

1.5 Other sources mortality

There may be some overrun of reported catch because of fish loss with trawl gear damage and ripped nets. In other orange roughy fisheries, a level of 5% has been estimated.

2. STOCKS AND AREAS

Orange roughy are distributed throughout the area. Spawning is known from several hills in the western Bay of Plenty as well as from features in the western regions of ORH 1. Stock status/affinities within the QMA are unknown. The Mercury-Colville grounds in the Bay of Plenty are about 120 n. miles from fishing grounds at East Cape (ORH 2A North), and spawning occurs at a similar time. Hence, it is likely that these are separate stocks. The Mercury and Colville Knolls in the Bay of Plenty are about 25 miles apart and may form a single stock. Stock affinities with other fishing hills in the southern and central Bay of Plenty are unknown. The Tauroa Knoll and outer Colville Ridge seamounts are distant from other commercial grounds, and these fish may also represent separate stocks.

3. STOCK ASSESSMENT

An assessment for the Mercury-Colville box was carried out in 2001 and is repeated here. A deterministic stock reduction technique (*after* Francis 1990) was used to estimate virgin biomass (B_0) and current biomass ($B_{current}$) for the Mercury-Colville orange roughy stock. The model was fitted to the biomass indices using maximum likelihood and assuming normal errors. In common with other orange roughy assessments, the maximum exploitation rate was set at 0.67. The model treats sexes separately, and assumes a Beverton-Holt stock-recruit relationship. Confidence intervals of the biomass estimates were derived from bootstrap analysis (Cordue & Francis 1994).

3.1 Estimates of fishery parameters and abundance

A series of trawl surveys of the Mercury-Colville box to estimate relative abundance were agreed under an Adaptive Management Programme. The first survey was carried out in June 1995 with a second survey in winter 1998 (Table 2). The biomass index of the latter survey was much lower than 1995, and because of warmer water temperatures it was uncertain whether the 1998 results were directly comparable to the 1995 results. They were not incorporated in the decision rule for the adaptive management programme. A third survey was carried out in June 2000, with the results suggesting that the abundance of orange roughy in the box had decreased considerably and was at low levels. However, these estimates are uncertain because of the suggestion that environmental factors may have influenced the distribution of orange roughy. The abundance indices from trawl survey and commercial catch-effort data used in the assessment are given in Table 2. The trawl survey indices had CVs of 0.27, 0.39 and 0.29 for 1995, 1998, and 2000 respectively.

Table 2: Biomass indices and reported catch used in estimation of B_0 . Values in square brackets are included for completeness; they are not used in the assessment.

Year	1993–94	1994–95	1995–96	1996–97	1997–98	1998–99	1999–00
Trawl survey	-	76 200	-	-	[2 500]	-	3 800
CPUE	8.3	9.1	5.4	4.2	[0.5]	1.5	(2.0)
Catch (t)	230	440	915	895	295	140	250

The CPUE series is mean catch per tow (sum of catches divided by number of tows, target ORH) from Mercury Knoll in the month of June. This is the only month when adequate data exist from the fishery to compare over time. A CV of 0.30 was assigned to the CPUE data.

Catch history information is derived from TCEPR records, scaled to the reported total catch for ORH 1. Overrun of reported catch (e.g., burst bags, inappropriate conversion factors) was assumed to be zero, as even if there was some, it is likely that it was similar between years. The catch in 1999–00 was assumed to be 250 t.

Assessments were carried out for three alternative sets of biomass indices (Table 3).

Table 3: Three alternative sets of biomass indices used in the stock assessment.

Alternative	Trawl survey indices	CPUE indices
1	1995, 2000	All except 1998
2	1995, 2000	None
3	1995, 2000	All except 1998 and 2000

Biological parameters used are those for the Chatham Rise stock, except for specific Bay of Plenty values for the maturity and recruitment ogives (Annala et al 2000).

3.2 Biomass estimates

The estimated virgin biomass (B_0) is very similar for all three alternative assessments (Table 4). With alternative 1 the estimated B_0 is 3200 t, with a current biomass of 15% B_0 . For both alternatives 2 and 3, the estimated B_0 is 3000 t, which is B_{min} , the minimum stock size which enables the catch history to be taken given a maximum exploitation rate of 0.67.

Table 4: Biomass estimates (with 95% confidence intervals in parentheses) for stock assessments with the three alternatives of Table 3. B_0 is virgin biomass; B_{MSY} is interpreted as B_{MAY} , which is 30% B_0 ; $B_{current}$ is mid-season 1999–00; and B_{beg} is the biomass at the beginning of the 2000–01 fishing year. Estimates are rounded to the nearest 100 t (for B_0), 10 t (for other biomasses), or 1%.

Biomass	Alternative 1		Alternative 2		Alternative 3	
B_0 (t)	3 200	(3 000, 3 600)	3 000	(3 000, 3 500)	3 000	(3 000, 3 300)
B_{MSY} (t)	960	(900, 1080)	900	(900, 1050)	900	(900, 990)
$B_{current}$ (t)	490	(290, 890)	290	(290, 790)	290	(290, 590)
$B_{current}$ (% B_0)	15	(10, 25)	10	(10, 23)	10	(10, 18)
B_{beg} (t)	480	(270, 900)	270	(270, 800)	270	(270, 590)

The model fits the CPUE data reasonably well but estimates a smaller decline than is implied by the two trawl survey indices.

3.3 Yield estimates and projections

Yield estimates were determined using the simulation method described by Francis (1992) and the relative estimates of MCY , E_{CAY} and MAY , as given by Annala et al (2000).

Yield estimates are all much lower than recent catches (Table 5). Estimates of current yields ($MCY_{current}$ and CAY) lie between 16 t and 35 t; long-term yields ($MCY_{long-term}$ and MAY) lie between 44 t and 67 t.

Table 5: Yield estimates (t) for stock assessments with the three alternatives of Table 3.

Yield	Alternative 1		Alternative 2		Alternative 3	
$MCY_{current}$	35	(22, 53)	22	(22, 51)	22	(22, 44)
$MCY_{long-term}$	47	(44, 53)	44	(44, 51)	44	(44, 49)
CAY	29	(16, 54)	16	(16, 48)	16	(16, 36)
MAY	67	(58, 70)	58	(58, 68)	58	(58, 64)

CSP for this stock is just under 100 t for any B_0 between 3000 t and 3600 t.

4. ANALYSIS OF ADAPTIVE MANAGEMENT PROGRAMME

The ORH 1 TACC was increased from 800 to 1400 t in October 2001/02 under the Adaptive Management Programme. The objectives of this AMP were to determine stock size, geographical extent, and long-term sustainable yield of the ORH 1 stock. This is a complex AMP, with ORH 1 divided into four sub-areas (see Figure 2), each with total catch and “feature” catch limits (Table 6) (a “feature” was defined as being within a 10 n. mile radius of the shallowest point).

Table 6: Description of control rules implemented in the ORH 1 AMP.

ORH 1 Subarea	Proposed Catch Limit	Feature Limit (t/fishing year)
Area A	200 t	100 t
Area B	500 t	150 t
Area C	500 t	150 t
Area D	200 t	75 t

Feature limits also serve as limits to the total catch in any area due to the limited number of available productive features. The Mercury-Colville “Box” (located within Area D) has been given a specific limit of 30 t per year to allow for the bycatch of orange roughy when fishing for black cardinalfish. The catch of orange roughy in the Mercury-Colville “Box” is included in the overall limit for Area D.

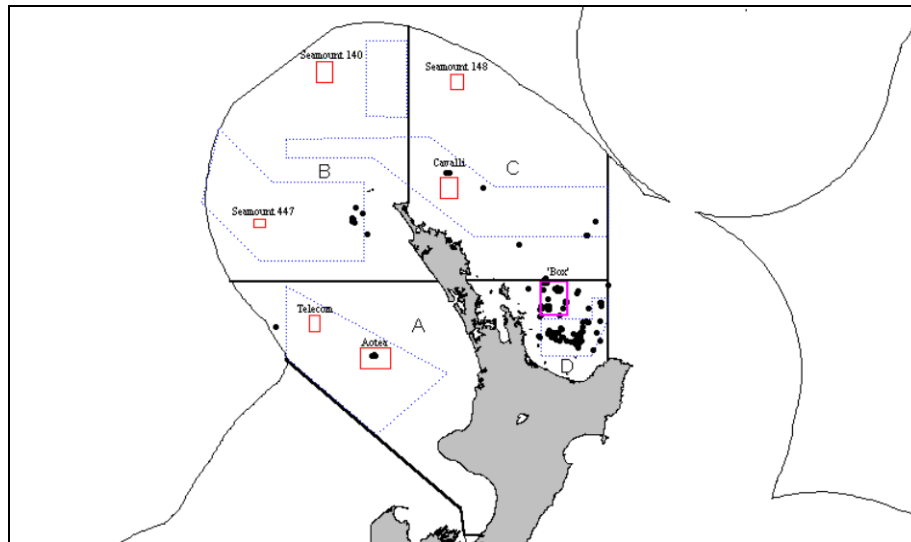

Figure 2: Four sub-management areas for the ORH 1 AMP (labelled A-D). Dotted lines enclose the exploratory fishing areas defined in the special permit issued on 6 July 1998. Solid lines enclose seamount closures and the Mercury-Colville Ohena 'box' (labelled at their top). Trawls (dots) where orange roughy were reported as the target species and caught during 1997-98 and 1998-99 are shown. Note that the lines separating Areas A and D from Areas B and C are incorrectly drawn at 36° S latitude rather than 35°30' S latitude.

From 1 October 2007 the stock is no longer part of the Adaptive Management Programme but stakeholders have agreed to continue with the sub-area and feature limits within the overall ORH 1 TACC.

Review of ORH 1 AMP in 2007

In 2007 the AMP FAWG reviewed the performance of the AMP after the full 5-year term.

Fishery Characterisation

- In most years, the total catch has been less than the TACC (Table 7).
- The area splits into A, B, C and D only occurred in 2001.
- Main fishery is in area B; the fishery in area A only began in 2002.
- Two main goals of the AMP:
 - Reduce fishing in area D, in particular the Mercury-Colville "box".
 - Look for new fishing areas, distributing effort across the QMA, with feature limits to reduce the possibility of localised overfishing.

Table 7: Estimated target catches by sub-area, scaled to landings, reported landings, and TACC for ORH 1. The scaling factor is calculated as reported catch/estimated (all target) catch (source: Anderson 2007b)

	Sub-area target catch (t)				Total target catch(t)	Reported landings (t)	TACC (t)	Scaling factor
	A	B	C	D				
1998	0.5	5.6	0.0	491.0	497	511	1 190	0.99
1999	5.2	575.2	165.0	724.5	1 470	1 543	1 190	0.99
2000	0.8	644.6	164.8	597.5	1 408	1 476	1 190	1.03
2001	8.5	166.3	99.4	164.6	439	858	800	1.11
2002	122.7	440.5	265.8	227.1	1 056	1 294	1 400	1.06
2003	196.7	508.1	237.9	72.2	1 015	1 123	1 400	0.98
2004	223.2	421.7	117.0	110.1	872	986	1 400	1.01
2005	277.0	389.8	173.4	174.1	1 014	1 151	1 400	1.13
2006	151.0	473.2	372.6	186.0	1 183	1 201	1 400	1.13

CPUE Analysis

- Unstandardised CPUE is in kg/tow. The short time series, the nature of the fishery (fishing aggregations spread over a wide area in different seasons) and the impact of catch limits on features and sub-areas prevent any useful relative abundance indices from being developed at this point for ORH 1.
- Where features are less than 10 n. mile apart, catch is apportioned according to the distance to the feature. Industry in-season reporting is based on the feature closest to the start of the tow.

ORANGE ROUGHY (ORH 1)

- Possible problems with the area A observations in 2005–06, as there seem to be more reported tows than expected given the number of vessels operating in the area.

Observer Programme

- 50% observer coverage prior to 1 October 2006 (a high level relative to that for other deepwater stocks, with a large number of samples taken relative to the size of the fishery). From 1 October 2006, 100% coverage was requested by the Minister, but this has not been fully achieved, as some ORH 1 is taken as bycatch on trips that do not predominantly target ORH.
- The size frequency data show high levels of stock variability between fisheries on features or feature groups. Size variation does not seem to be linked to exploitation rate.

Environmental Effects

- Observer data from 2000 to 2003 indicated that incidental captures of seabirds did not occur in the ORH 1 target fishery (Baird 2005). Marine mammal interactions are also not a problem.
- Only three non-fish bycatch records have been reported from observed trips (in 1994 and 1995). All were shearwaters that landed on deck and were released alive. It was verified that observers were briefed in the same way as for other MFish trips including recording non-fish bycatch i.e. seabirds and marine mammals. Note that this does not include benthic organisms.
- The overall impact of bottom trawling on seamounts in ORH 1 is not known. A number of seamounts have been closed to fishing and the Norfolk Deep BPA is included in the industry accord relating to benthic protection areas within New Zealand's EEZ.

Sub-area D Directed Adaptive Exploratory Fishing Programme

- The purpose of this exercise was to establish whether fish populations shift between features in different years in sub-area D.
- Based on the results from the exploratory fishing from 2002 to 2005 it is evident that catches from all features contained a high proportion of ripe or ripe running females and that synchronised spawning occurs on a range of hills during winter.
- In 2006 the AMP Working Group recommended some changes to the design of the exploratory survey; however, this was not achieved during the 2006 survey.

The abbreviated checklist questions for full- and mid-term reviews are:

1. Is stock abundance adequately monitored?
The working group concluded that CPUE does not seem to be a proportional measure of abundance for this stock. However, CPUE is used in ORH 1 as a management tool. When CPUE drops on a feature, fishers are meant to move to another feature.
2. Is logbook coverage sufficient?
As there are Ministry fisheries observers on these vessels, fishers are not required to complete detailed logbooks for the AMP. This is the highest level of monitoring of any ORH fishery in New Zealand.
3. Are additional analyses of current data necessary?
No. The Working Group concluded that no other information can currently be extracted from the existing data that will provide insight into the status of the ORH 1 stocks. However, a potential problem with the 2005–06 catch records from Area A still needs to be checked.
4. Based on the biomass index, is current harvest sustainable?
Unknown. The purpose of the AMP was to spread effort in an attempt to reduce fishing pressure on any one sub-area or feature (and Area D in particular). ORH 1 is a large area, with orange roughy aggregations spread across a number of areas and features. The amount of fishing in some areas appears to be low, but without any indication of current abundance, there is no way to determine if this level of fishing is in fact sustainable, or if current feature limits will avoid overexploitation of localised areas.
5. Where is stock, based on weight of evidence, in relation to B_{MSY} ?
Unknown. In 2001, when the AMP was initiated, the Working Group stated that the stock was likely to be above B_{MSY} ; while the information collected since that time has

not improved the understanding about the status of the stock, the intent of the AMP design for ORH 1 was to spread effort to reduce the likelihood of the biomass declining below B_{MSY} .

ORH 1 is unlikely to be a single biological stock, and probably includes a number of constituent stocks. The Working Group concluded that it is not possible to estimate B_{MSY} for any of the individual stocks, let alone aggregate up to an estimate for ORH 1 as a whole. Moreover, a better understanding is not possible in the near future. B_{MSY} is difficult to estimate in situations involving an unknown number of constituent stocks.

6. Are the effects of fishing adequately monitored?

Yes, there is good observer coverage. The Working Group noted that one consequence of deliberately spreading effort was to increase the possible benthic impact.

7. Are rates of non-fish bycatch acceptable?

Yes.

8. Should the AMP be reviewed by the Plenary?

This AMP does not need to be reviewed by the Plenary.

5. STATUS OF THE STOCKS

From 1 October 2001, the TACC for ORH 1 was increased to 1 400 t within the AMP, with sub-area and feature limits. From 1 October 2007 the stock is no longer part of the Adaptive Management Programme but stakeholders have agreed to continue with the sub-area and feature limits within the overall ORH 1 TACC.

In most years the total catch has been less than the TACC. However, it is not known if recent catch levels or current TACCs are sustainable in the long term. Except for the small area of the Mercury-Colville box no assessment of stock status is currently available.

An assessment of the Mercury-Colville box in 2001 indicated that biomass had been reduced to 10-15% B_0 (compared to an assumed B_{MSY} of 30% B_0). As the stock was considered to be well below B_{MSY} , a catch limit of 30 t was set for the box. The assessment indicated that a catch level of about 100 t would probably maintain the stock at the 2000 stock size (assuming deterministic recruitment) and catch levels from 16 to 35 t (consistent with *CAY* or *MCY* strategies) might allow the stock to rebuild slowly.

In other areas of ORH 1 the status of the constituent stocks is unknown. The amount of fishing in some areas appears to be low, but without any indication of current abundance, there is no way to determine if this level of fishing is in fact sustainable or if current feature limits will avoid overexploitation of localised areas.

ORANGE ROUGHY, CAPE RUNAWAY TO BANKS PENINSULA (ORH 2A, 2B, 3A)**1. FISHERY SUMMARY****1.1 Commercial fisheries**

The first reported landings of orange roughy between Cape Runaway and Banks Peninsula were in 1981–82 occurring with the development of the Wairarapa fishery. Total reported catches and TACCs grouped into the three orange roughy Fishstocks from 1981–82 to 2016–17 are shown in Table 1. The historical catches and TACCs for these stocks are shown in Figure 1.

Table 1: Reported catches (t) and TACCs (t) from 1981–82 to 2016–17. QMS data from 1986–present.

Fishing Year	QMA 2A (Ritchie + E.Cape)		QMA 2B (Wairarapa)		QMA 3A (Kaikoura)		All areas combined TACC or catch limit	
(1 Oct–30 Sep)	Catches	TACC	Catches	TACC	Catches	TACC	Catches

* Ministry data † FSU data. § Included in QMA 3B TAC.

In 2012/13, shelving (an agreement that transfers ACE to a third party to effectively reduce the catch without adjusting the TACC) occurred (ORH 2A 165 t, ORH 2B 34 t and ORH 3A 101 t)

There was a major change in the ORH 2A fishery in 1993–94 with a shift of effort from the main spawning hill on Ritchie Bank to hills off East Cape. Although these hills had apparently only been lightly fished in the past, during 1993–94 52% of the total catch from ORH 2A was taken from the East Cape area (Table 2). This led to an agreement between industry and the Minister responsible for fisheries that, from 1994–95, the traditionally fished areas within ORH 2A (south of 38°23', hereafter referred to as “2A South”) would be managed separately from the new East Cape fishery (north of 38°23', “2A North”). ORH 2A South was combined with ORH 2B and ORH 3A to form the Mid-East Coast (MEC) stock for management purposes.

The catch limits for these two areas changed three times in the following four years, including a subdivision of 2A North (Table 3). Catches in the exploratory sub-area of 2A North never approached the catch limit, with only 37 t being caught in 1996–97 and less in subsequent years.

ORANGE ROUGHY (ORH 2A, 2B, 3A)

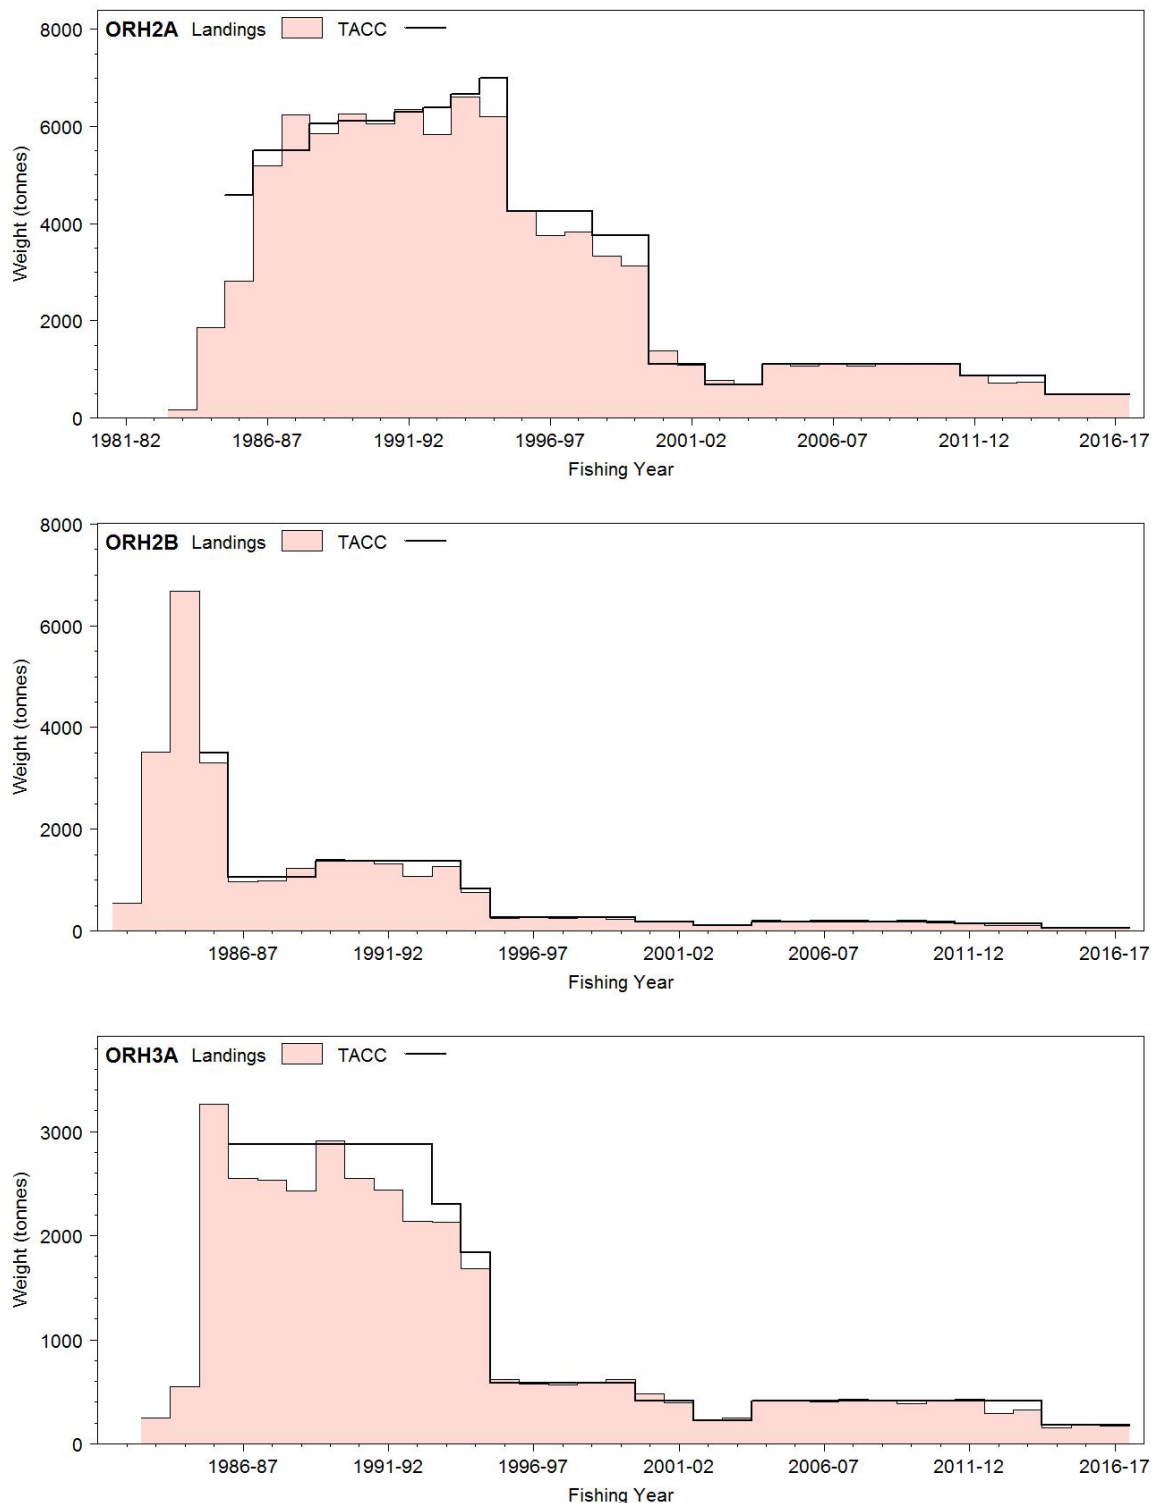

Figure 1: Reported commercial landings and TACCs for ORH 2A (Central (Gisborne)), ORH 2B (Central (Wairarapa)), and ORH 3A (Central/Challenger/South-East (Cook Strait/Kaikoura)).

For the 2000–01 fishing year, the TACC for ORH 2A was reduced to 1 100 t, that for ORH 2B to 185 t, and that for ORH 3A to 415 t. Within the TACC for ORH 2A, the catch limit for all of 2A North was reduced to 200 t, without specifying separate catch limits for the East Cape Hills and the exploratory area, while the catch limit for 2A South was reduced to 900 t. This gave a catch limit for the MEC stock of 1 500 t. The catch limit for MEC was reduced to 800 t (and ORH 2A South to 480 t) for the 2002–03 and 2003–04 fishing years. From 1 October 2004 there was an increase in the TACC to 1 100 t, 185 t,

and 415 t in 2A, 2B, and 3A respectively. Furthermore, an allowance of 58 t, 9 t, and 21 t, for other mortality was allocated to 2A, 2B, and 3A in 2004 as well.

In 2012–13 the fishing industry voluntarily shelved (an agreement that transfers ACE to a third party to effectively reduce the catch without adjusting the TACC) approximately 25% of the MEC quota, resulting in effective catch limits of 510 t, 106 t, and 314 t for 2A South, 2B, and 3A respectively.

1.2 Recreational fisheries

Recreational fishing for orange roughy is not known in this area.

1.3 Customary non-commercial fisheries

No information on customary non-commercial fishing for orange roughy is available for this area.

1.4 Illegal catch

No information is available about illegal catch in this area.

Table 2: North Mid-East Coast + East Cape (ORH 2A) catches by area, in tonnes and by percentage of the total ORH 2A catch. (Percentages up to 1993–94 and from 2007–08 calculated from Ministry data; 1994–95 to 1996–97 from NZFIB data, and 1997–98 to 2016–17 from Orange Roughy Management Co.) Mid-East Coast (MEC) stock (ORH 2A South, ORH 2B, and ORH 3A combined) catches in tonnes.

1.5 Other sources of mortality

There has been a history of catch overruns in this area because of lost fish and discards, particularly in the early years of the fishery. In the assessments presented here total removals were assumed to exceed reported catches by the overrun percentages in Table 4.

All yield estimates and forward projections presented make an allowance for the current estimated level of overrun of 5%.

Table 4: Catch overruns (%) by QMA and year. -, no catches reported.

2. BIOLOGY

Biological parameters used in this assessment are presented in the Biology section at the beginning of the Orange Roughy Introduction section.

3. STOCKS AND AREAS

Two major spawning locations have been identified in ORH 2A, one at the East Cape Hills in “2A North” and the other on the Ritchie Bank in “2A South”. Spawning orange roughy were located in Wairarapa (ORH 2B) in winter 2001, but no large concentrations were found, and the significance of this spawning event is not known. Spawning orange roughy have not been located in Kaikoura (ORH 3A). The major spawning area in ORH 2A South, ORH 2B, and ORH 3A is still believed to be the Ritchie Bank, although spawning aggregations were not seen here in the 2013 AOS survey.

Results from allozyme studies showed that orange roughy from the three areas, “2A South”, Wairarapa, and Kaikoura could not be separated, but were distinct from fish on the eastern Chatham Rise. Earlier analyses that suggested there was a genetic stock boundary between East Cape and Ritchie Bank were not supported by a more recent replicate sample from East Cape. For these reasons, orange roughy in this region are currently treated as two stocks: the Mid-East Coast (MEC) stock (2A South, Wairarapa, and Kaikoura) and the East Cape (EC) stock (2A North). The relationship between these areas and the location of the main fishing grounds is shown in Figure 2.

4. STOCK ASSESSMENT

Stock assessments are reported below for East Cape from 2003 and for Mid-East Coast (MEC) from 2014. In 2018 there was a preliminary update of the MEC stock assessment (Cordue 2017). The stock status and biomass trajectories from the preliminary stock assessment did not change or revise those reported for the 2014 assessment (Cordue 2014b). Because of the similarity in results, rather than report the preliminary results from the 2018 assessment, the 2014 assessment was retained in this report.

4.1 East Cape stock (2A North)

The stock assessment for the East Cape was last updated in 2003 and is summarised here (Anderson 2003b). An attempt to update the assessment with a new set of CPUE indices was made in 2006, but was rejected by the Working Group because of changes in the fishery which invalidated the utility of the CPUE series as an index of abundance. With no other abundance estimates available, an updated stock assessment was not possible.

4.1.1 Assessment Inputs

A CPUE analysis was performed in 2006, but was considered unreliable because of a change in fishing patterns and fleet size corresponding to the reduction of the catch limit to 200 t in 2000–01. The CPUE analysis was updated in 2011 and was considered more reliable by the Working Group due to the increase in the number of trawls per year since 2006. The 2011 analysis showed that standardised CPUE decreased after a peak in 2003–04, and has subsequently remained at a level similar to that in the late 1990s to early 2000s (Table 5).

Previous concerns by the Working Group that the fishery was dominated by a single vessel were alleviated somewhat by the return or entry of three other vessels to the fishery since 2003–04, but the utility of CPUE analyses in fisheries where substantial catch limit reductions have caused major changes in fishing patterns remains an issue for this stock.

The model inputs for the 2003 stock assessment were catches, an egg survey, and CPUE indices (Table 5). The biological parameters used are presented in the Biology section at the beginning of the Orange Roughy section.

ORANGE ROUGHY (ORH 2A, 2B, 3A)

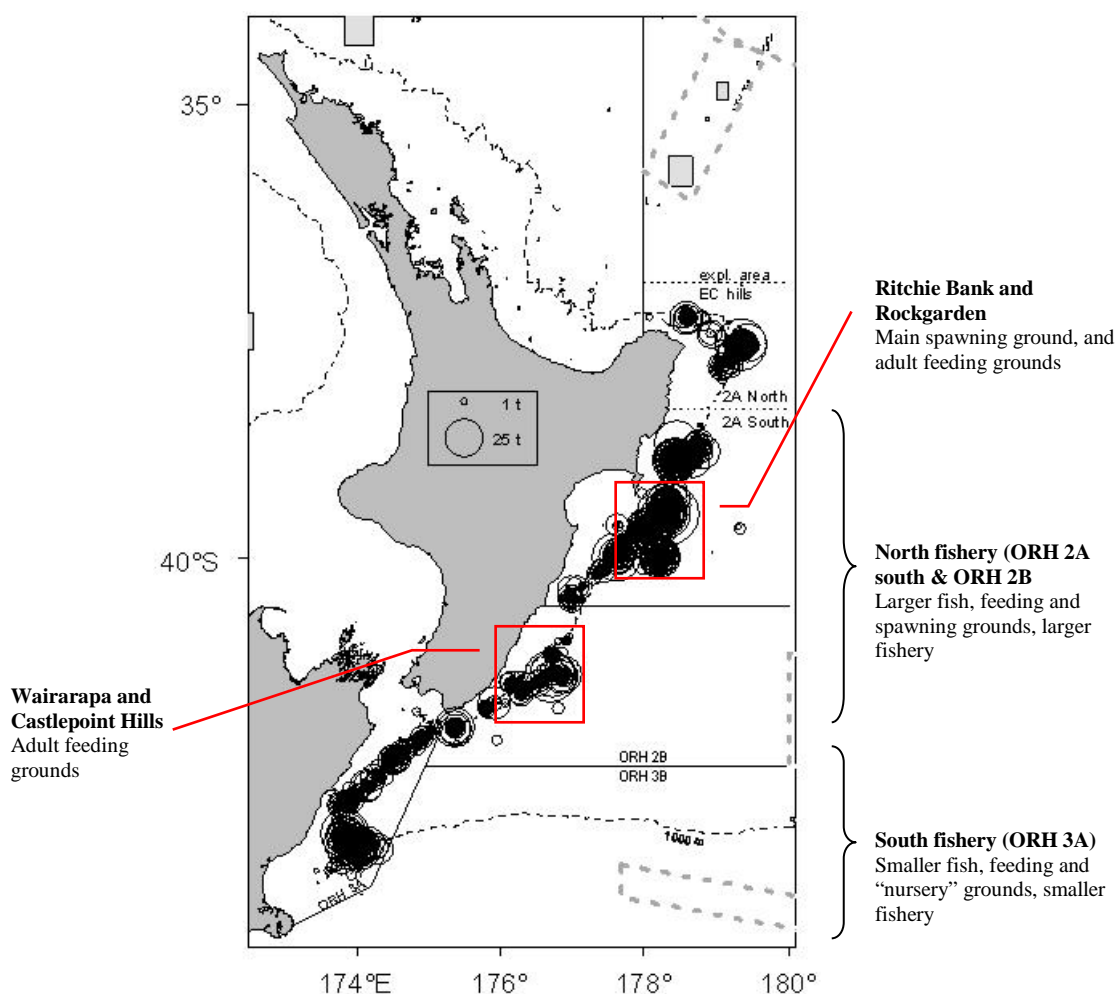

Figure 2: Catch (t) per tow of orange roughy in ORH 2A, ORH 2B, and ORH 3A for the five fishing years from 2006–07 to 2010–11 (circles, with area proportional to catch size), location of the fisheries assumed during stock assessment, and the location of the main spawning, feeding, and nursery grounds. Perimeters of Benthic Protection Areas (BPAs) closed to bottom trawling are marked with dashed grey lines, and seamounts closed to trawling are marked as shaded rectangles.

Table 5: Standardised CPUE and egg survey indices, and CVs for the East Cape stock, as used in the 2003 assessment, and an updated standardised CPUE index derived in 2011. -, no data.

	CPUE index 2003	CV(%)	Egg survey	CV(%)	CPUE index 2011	CV(%)
1993–94	1.00	12	-	-	0.95	23
1994–95	0.69	8	29 000	69	0.76	22
1995–96	0.60	8	-	-	0.61	23

2000–01	0.21	15	-	-	0.28	26
2001–02	0.22	16	-	-	0.23	27
2002–03	-	-	-	-	0.51	32
2003–04	-	-	-	-	0.50	30
2004–05	-	-	-	-	0.29	27
2005–06	-	-	-	-	0.37	28
2006–07	-	-	-	-	0.36	29
2007–08	-	-	-	-	0.27	28
2008–09	-	-	-	-	0.24	28
2009–10	-	-	-	-	0.20	27

4.1.2 Stock assessment

A stock assessment analysis for the East Cape stock was performed in 2003 using the stock assessment program, CASAL (Bull et al 2002) to estimate virgin and current biomass.

- The model was fitted using Bayesian estimation and partitioned the EC stock population by sex,

maturity (the fishery was assumed to act on mature fish only) and age (age-groups used were 1–70, with a plus group).

- The model estimated virgin biomass, B_0 , and the process error for the CPUE indices. Catchability, q , was treated as a nuisance parameter by the model.
- The stock was considered to reside in a single area, and to have a single maturation episode modelled by a logistic-producing ogive where 50% of fish of both sexes were mature at age 26 and 95% at age 29.
- The catch equation used was the instantaneous mortality equation from Bull et al (2002) whereby half the natural mortality was applied, followed by the fishing mortality, then the remaining natural mortality.
- The size at age model used was the von Bertalanffy.
- No stock recruitment relationship was assumed.
- A Bayesian estimation procedure was used with a penalty function included to discourage the model from allowing the stock biomass to drop below a level at which the historical catch could not have been taken.
- Lognormal errors, with known (sampling error) CVs were assumed for the CPUE and egg survey indices. Additionally, process error variance was estimated by the model and added to the CVs from the CPUE indices.
- Confidence intervals were calculated from the posterior profile distribution of B_0 estimates, where the process error parameter was fixed at the value previously estimated.

4.1.3 Biomass estimates

Biomass estimates for this stock are given in Table 6 and the biomass trajectories, plotted against the scaled indices, are shown in Figure 3. The base case assessment of the EC stock included only the CPUE indices. An alternative assessment was carried out including the point estimate of biomass from the 1995 egg survey along with the CPUE indices. The CPUE indices agree well with the biomass estimates, with only the 1993–94 and 1997–98 indices departing from the biomass 95% confidence intervals. The egg survey biomass estimate, with the large associated CV, has little effect on the biomass trajectory.

Table 6: Estimates of virgin biomass (B_0), B_{MSY} (calculated as B_{MAY} , the mean biomass under a CAY policy), and B_{2003} , for the EC stock (with 95% confidence intervals in parentheses).

Assessment	Index	B_0 (t)		B_{MSY} (t)	B_{2003}	
		(t)	% B_0		(t)	% B_0
Base case	CPUE	21 100 (19 650–23 350)	6 300	5 100	24	(20–32)
Alternative	CPUE + Egg survey	21 200 (19 700–23 550)	6 380	5 200	25	(20–33)

The base case estimate of $B_{CURRENT}$ (the mid-year biomass in 2002–03) is 5100 t (24% B_0) with a 95% confidence interval of 3800 to 7550 t. This is almost twice the value of B_{2003} estimated for mid-year 1999–2000 in the previous assessment (Anderson 2000). The alternative assessment gives a very similar estimate of B_{2003} .

Figure 3: Estimated biomass trajectories for the base case and alternative model runs for the EC stock. Annual biomass estimates are mean posterior density (MPD) values and 95% confidence intervals (grey dashed lines) are calculated from the posterior profile distribution of B_0 estimates. The CPUE index CVs (sampling error plus process error) are shown, as is the CV calculated for the egg survey biomass estimate.

4.1.4 Yield estimates and projections

Estimates of *MCY* and *CAY* for the *EC* stock were calculated from large numbers of simulation runs using posterior profile sampling of B_0 and a series of trial harvest levels. These estimates, together with *MAY* (the mean catch with a *CAY* harvesting strategy) and *CSP* (current surplus production) are given in Table 7. *CSP* is driven by recruitment of fish spawned before the fishery began.

Table 7: Estimates of *MCY*, *CAY*, *MAY*, and *CSP* for the *EC* stock, with 95% confidence intervals in parentheses (all corrected for an assumed overrun of 5%).

Assessment	<i>MCY</i> (t)	<i>CAY</i> (t)	<i>MAY</i> (t)	<i>CSP</i> (t)
Base case	350	370	410	550
Alternative	350	370	410	550

4.2 Mid-East Coast stock (2A South, 2B, 3A)

There was no new information available that would change the accepted stock definition of the MEC orange roughy stock i.e. comprising ORH 2A South, ORH 2B, and ORH 3A.

The Mid-East Coast (MEC) stock assessment was updated in 2014 using the methods common to the four assessments performed in 2014 (see Orange Roughy Introduction). The previous model based assessment was in 2013 but that assessment used data which did not meet the quality threshold applied in 2014 (i.e., CPUE indices, wide-area acoustic survey and egg-survey estimates). In 2014, an age-structured population model was fitted to the data described in Section 4.2.2 below.

4.2.1 Model structure

The model was single-sex and age-structured (1–120 years with a plus group) with maturity in the partition (i.e., fish were classified by age and as mature or immature). A single area and a single time step were used with two year-round fisheries defined by different selectivities (a “southern” fishery catching young fish (double-normal selectivity) and a “northern” fishery catching older fish (logistic selectivity)). The spawning season was assumed to occur after 75% of the mortality and 100% of mature fish were assumed to spawn each year.

The catch history was constructed from the catches in Tables 1 and 2, adding the catch over-run percentages in Table 4. The northern fishery combined catches from ORH 2A South and ORH 2B, and the southern fishery used ORH 3A. Natural mortality was assumed to be fixed at 0.045 and the stock-recruitment relationship was assumed to follow a Beverton-Holt function with steepness of 0.75. The remaining fixed biological parameters are given in the Orange Roughy Introduction.

4.2.2 Input data and statistical assumptions

There were three main data sources for observations fitted in the assessment: a spawning biomass estimate from an acoustic survey (2013); a trawl-survey time series of relative biomass indices (1992–1994, 2010) with associated length frequencies (1992, 1994), and age frequencies and estimates of proportion spawning at age (1993, 2010); and length and age frequencies collected from the commercial fisheries, including four spawning-season age frequencies (1989–1991, 2010).

Research surveys

The MEC area has been surveyed using acoustic and trawl methods, and egg surveys have also been conducted. Not all survey data have been used in the 2014 assessment. The egg survey estimates have some quality issues associated with them; the 1993 survey data were post-stratified and “corrected” for turn-over of fish (Zeldis et al 1997). The 1993 egg-survey estimate was used in the 2013 assessment but was not considered to be reliable enough for the 2014 assessment (which had a higher “quality threshold”). Similarly, the wide-area acoustic survey estimates from 2001 and 2003 (Doonan et al 2003, 2004a) were rejected in 2014 as being not sufficiently reliable (in particular, the biomass estimates primarily came from mixed species marks and “orange roughy” marks identified subjectively; rather than being from easily identified spawning plumes).

Trawl survey data

A time series of pre-spawning season, random, stratified, trawl surveys were conducted in March–April on *RV Tangaroa* in 1992–94 and 2010 (Grimes et al 1994, 1996a, 1996b; Doonan & Dunn 2011). The 2010 survey was specifically designed to be comparable with the earlier surveys and to produce an abundance index for the MEC home grounds (Doonan & Dunn 2011). In addition to the relative biomass indices (Table 8), the survey data were analysed to produce length frequencies from all years and age frequencies from 1993 and 2010 (Doonan et al 2011). Also, estimates of female proportion spawning at age were produced for the 1993 and 2010 surveys (Ian Doonan, pers. comm.).

Table 8: Biomass indices and CVs used in the stock assessment.

Year	Trawl index (t)	CV (%)	Acoustic index (t)	CV (%)
1992	20 838	29		
1993	15 102	27		
1994	12 780	14		
2010	7 074	19		
2011				
2012				
2013			4 225	20

The biomass indices were fitted as relative biomass with a double-normal selectivity (it is apparent that the trawl survey did not fully select the largest/oldest fish) and an uninformed prior on the proportionality constant (q). The length frequencies from 1992 and 1994 were fitted as multinomial, as were the age frequencies from 1993 and 2010 (length frequencies from 1993 and 2010 had been used in the production of the age frequencies). The proportion spawning at age was assumed binomial at each age. Effective sample sizes were all taken from the 2013 assessment (Cordue 2014).

Acoustic survey estimate

The only reliable acoustic estimate of spawning biomass for MEC came in 2013 when a multi-frequency “AOS” survey was conducted (acoustic and optical gear mounted on the trawl headline, e.g., see Kloser et al 2011). Four areas were visited in 2013 but the only substantial spawning plume was seen in the “Valley” (a known spawning site near Ritchie Bank). Four snapshots were taken and the estimates from 38 kHz were averaged to produce a biomass index (Table 8).

The “standard” assumption in the 2014 stock assessments, for acoustic estimates from spawning plumes, is that they collectively cover “most” of the spawning biomass where “most” is taken to be 80%. However, for MEC, only one spawning plume was found and it was in a very small area. There are many potential sites in the MEC for spawning plumes. For these reasons, “most” was taken to be 60% in the base model (and sensitivities were done at 40% and 80%). That is, the acoustic estimate was fitted as relative biomass with an informed prior: lognormal (mean = 0.6, CV = 19%) for the base model.

Commercial age and length frequencies

As in 2011 and 2013, composition data were also used: length frequency samples from the northern commercial fishery (ORH 2A South and ORH 2B) for 16 years between 1988–89 and 2009–10, and from the southern commercial fishery (ORH 3A) for nine years between 1989–90 and 2008–09, and age frequency samples from commercial landings of the spawning fishery in ORH 2A south in 1989, 1990, 1991. The otoliths from the 1989–91 samples were re-aged for the 2013 assessment using the new ageing protocol (Tracey et al 2007). In addition, age samples taken from a single vessel in the 2010 spawning season were also used. These had been aged with the new protocol but because they were from a single vessel and a fishery 20 years later than in 1990 the age frequency was fitted with its own selectivity. The age frequencies from 1989–91 were assumed to be from spawning fish (i.e., no selectivity fitted). The composition data were all assumed to be multinomial and effective sample sizes from the 2013 assessment were used (except the southern fishery length frequencies were down-weighted following the iterative reweighting procedure of Francis (2011)).

4.2.3 Model runs and results

In the base model, natural mortality (M) was fixed at 0.045. There were numerous MPD sensitivity runs and six main sensitivities are presented in this report: estimate M ; down-weight the trawl indices; separate selectivity for spawning age frequencies; mean acoustics q prior = 0.4; and the *LowM-Highq* and *HighM-Lowq* “standard” runs (see Orange Roughy Introduction).

In the base model, the main parameters estimated were: virgin biomass (B_0), the maturity ogive, the two fishery selectivities, the trawl survey selectivity, the 2010 age frequency selectivity, and year class strengths (YCS) from 1881 to 1996 (with the Haist parameterisation and “nearly uniform” priors on the free parameters). Additional estimated parameters included the CV of the length-at-age parameters and the proportionality constants (qs) for the trawl survey time series and the 2013 acoustics estimate.

Model diagnostics

The MPD fits to the biomass indices were excellent (Figure 4), although the MCMC fit was only just adequate for the trawl survey indices, particularly to the 2010 index (Figure 5). The poorer MCMC fit to the 2010 trawl index when compared to the MPD fit occurred because the MPD pattern of YCS did not match the posterior distribution of the same quantities, showing much greater year-to-year variation than seen in the MCMC posterior (Figure 6). This result highlights the difference between MPD estimates and MCMC estimates: the MPD finds the single vector of parameters which give the best fit to the data, while the MCMC procedure finds the parameter space that best explains the data. There is no reason why the MPD has to be in the “middle” of the posterior distribution, here we have an example where the MPD estimates are in the tail of the posterior distribution.

The MCMC fit to the acoustics index had also degraded when compared to the MPD fit (see Figures 4 and 5), as well as estimating a lower acoustics q (Figure 7). The cause of this is the same as for the 2010 trawl index; the MPD spawning biomass trajectory almost exactly matched the 2013 acoustic estimate but, given the less variable MCMC YCS trajectory, the resulting MCMC biomass trajectory was shifted higher (and the acoustic q shifted lower to compensate).

Figure 4: MPD fit to biomass indices: left: acoustic-survey spawning biomass index (fitted with an informed q prior, mean = 0.6; MPD estimated q = 0.59); right: *Tangaroa* trawl-survey indices. Vertical lines are 95% CIs.

Figure 5: MCMC base: normalised residuals for the biomass indices. The box covers 50% of the distribution for each index and the whiskers extend to 95% of the distribution. “Aco” denotes the acoustic estimate (2013). “Trawl” denotes the *Tangaroa* trawl-survey time series (1992–94, 2010).

Figure 6: Base model: MCMC estimated “true” YCS (R_t/R_0) (in black). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The MPD estimates are shown in red.

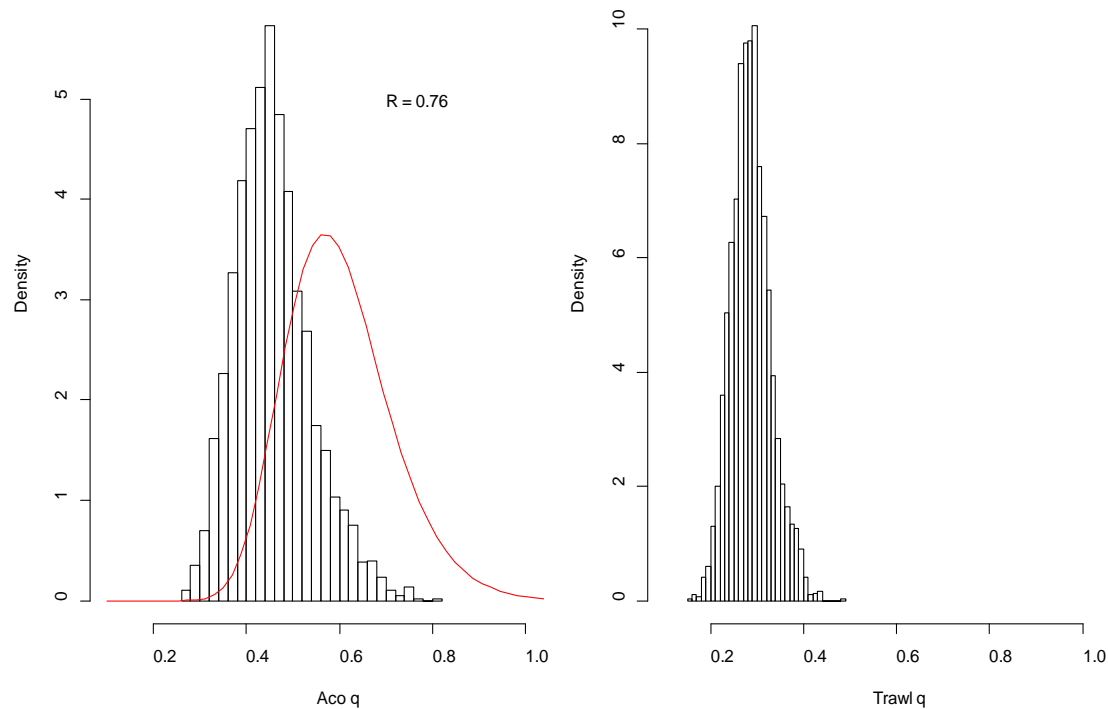

Figure 7: Base model MCMC diagnostics: prior and posterior distributions for the acoustic q (prior in red, posterior black histogram) (left); posterior distribution for the trawl-survey q (the prior was uninformed) (right). $R = 0.76$ is the ratio of the mean of the acoustic q posterior to the mean of the prior.

The MPD fits to the commercial length frequencies were adequate (Figures 8 and 9). They could never be very good because the length frequencies show a great deal of year-to-year variability, as evidenced by the annual mean lengths (Figure 10). The model predictions of annual mean length are necessarily fairly smooth from year-to-year; as they are only able to track the main trend but not the annual jumps (Figure 10).

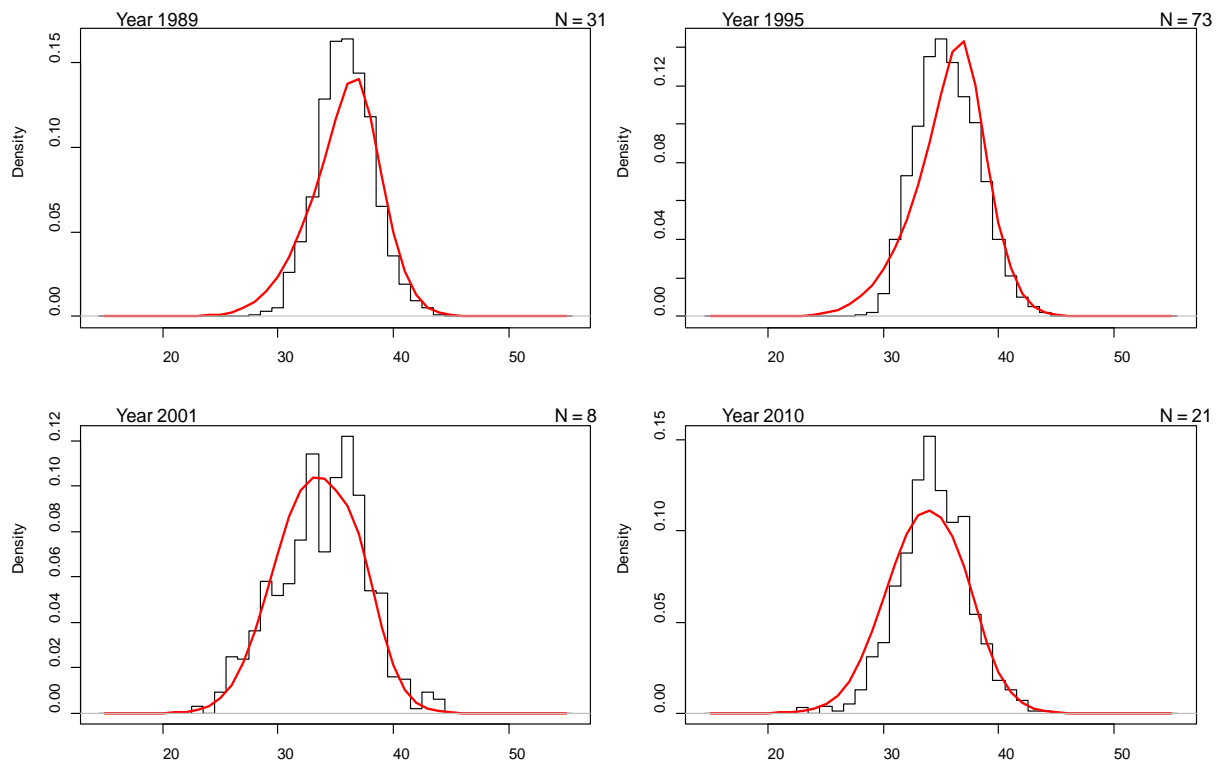

Figure 8: Example MPD fits to northern fishery length frequencies (N is the assumed effective sample size in the given year; x-axis is fish length (cm)). Observations are black lines; model predictions are the red lines.

ORANGE ROUGHY (ORH 2A, 2B, 3A)

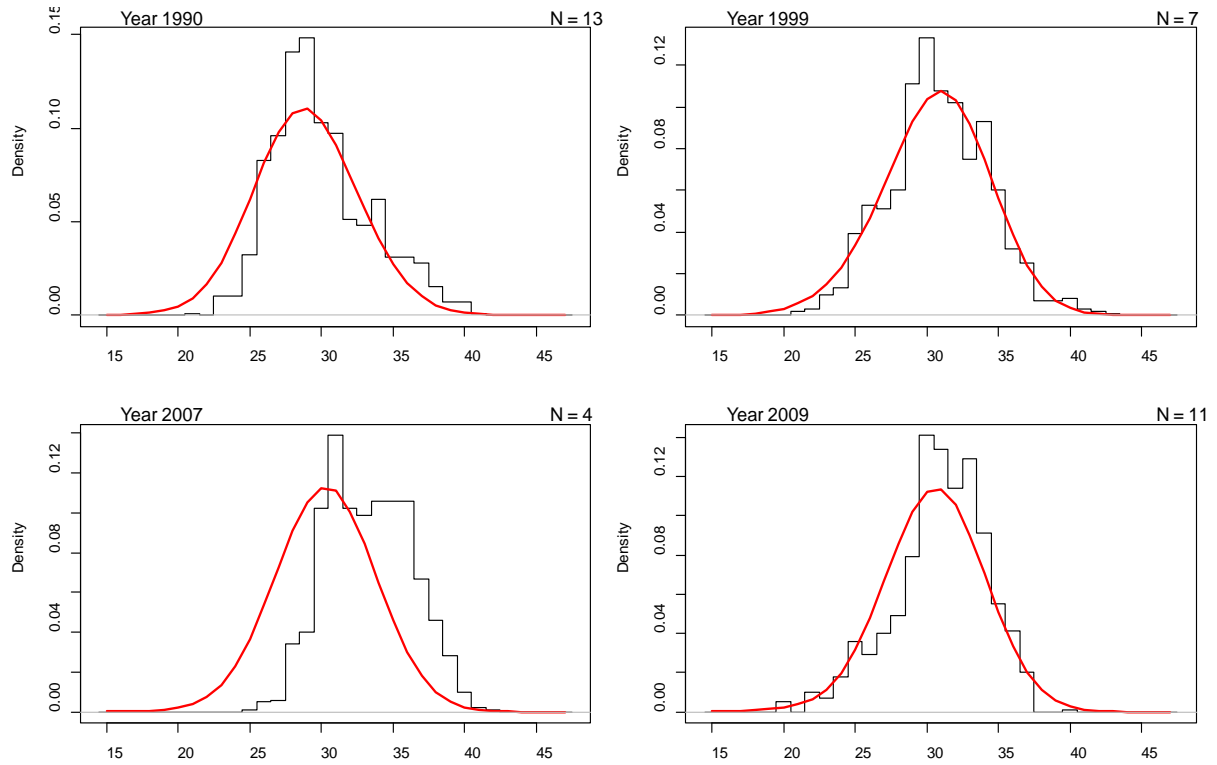

Figure 9: Example MPD fits to southern fishery length frequencies (N is the assumed effective sample size in the given year; x axis is fish length (cm)). Observations are black lines; model predictions are the red lines.

Figure 10: Annual mean lengths from the commercial length frequencies (northern fishery on the left, southern on the right) with 95% CIs (black, circles, dashed vertical lines) and the base model predictions (red, triangles, solid lines).

The MPD fits to the trawl-survey length frequencies and estimates of proportion spawning at age are good (Figure 11). It is notable that the model fits the different shape of the proportion spawning estimates in 1993 and 2010 (Figure 11). The spawning-season age frequencies are only adequately fitted (Figure 12). There is a misfit for the young ages (except for 2010 which had its own selectivity) as these data compete with the proportion spawning-at-age data to define the maturity ogive (see Figure 11 – young fish are spawning according to the proportion spawning data). In response to the misfit in Figure 12, a sensitivity run was done where the 1989–91 spawning age frequencies were allowed to have a logistic selectivity. This improved the fit substantially and raised the model estimate of the 2014 stock status from 14 to 17% B_0 . The base model was preferred to be consistent across the four orange roughy stocks assessed in 2014, with the maturity ogive used to define the spawning-season selectivity and age frequencies.

The fit to the trawl-survey age frequencies is excellent, which should be expected given the large effective sample size of $N = 200$ (Figure 13). A number of sensitivity runs were done with alternative data weighting, including down-weighting the trawl-survey age frequencies, which demonstrated that the model was robust to a wide range of assumptions. For example, the only runs that made a substantial difference to the MPD estimates of stock status were doubling the acoustic index (10.2% B_0 compared to the base estimate of 6.5% B_0) and assuming deterministic recruitment (25.8% B_0); the other 16 runs had MPD estimates in the range 4–9% B_0 .

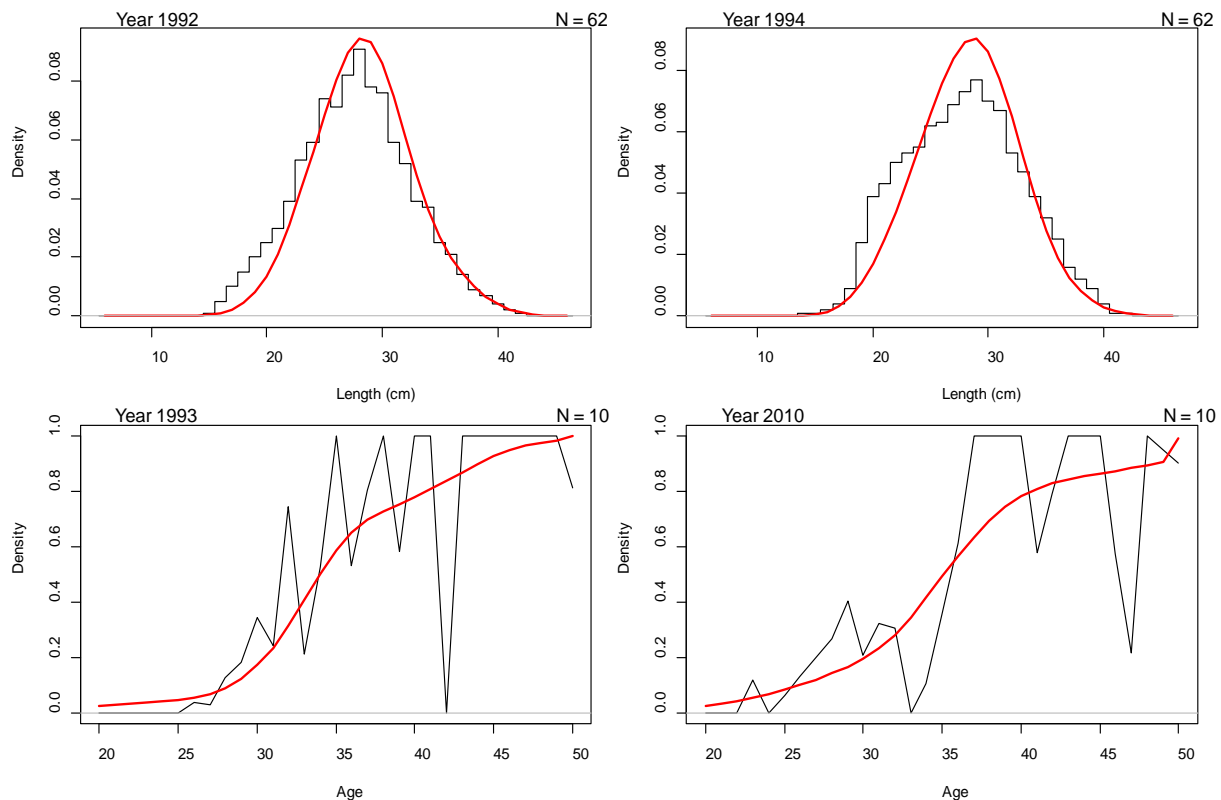

Figure 11: Base, MPD fits to trawl-survey length frequencies (N is the assumed effective sample size in the given year) and proportion spawning-at-age ($N = 10$ is the binomial sample size assumed for each age). Observations are black lines; model predictions are the red lines.

ORANGE ROUGHY (ORH 2A, 2B, 3A)

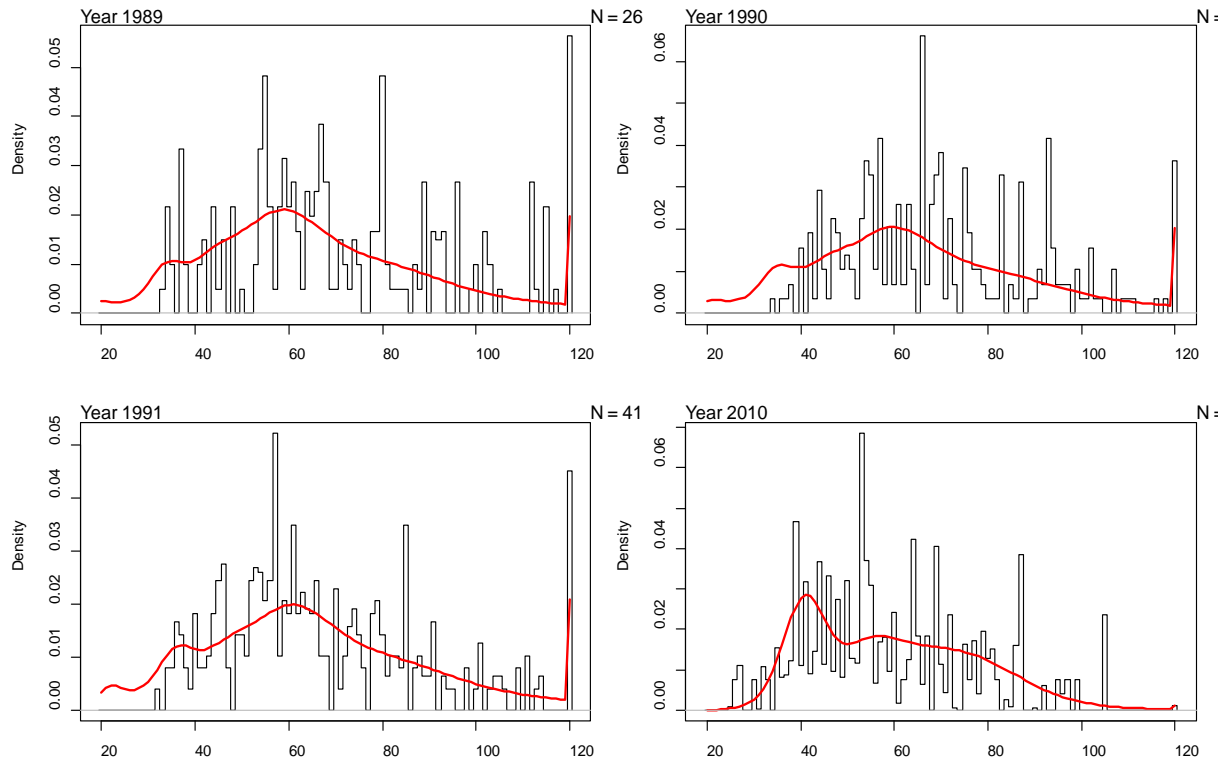

Figure 12: Base, MPD fit to spawning-season age frequencies (N is the assumed effective sample size in the given year). Observations are black lines; model predictions are the red lines.

Figure 13: Base, MPD fit to trawl-survey age frequencies (N = 200 is the assumed effective sample size). Observations are black lines; model predictions are the red lines.

MCMC results

MCMC convergence diagnostics were very good for the base model and sensitivities. Virgin biomass (B_0) was estimated to be about 100 000 t for all runs (Table 9). Current stock status was similar for the base and the estimate- M run (Table 9). The slightly lower stock status when M was estimated reflects the lower estimate of M (0.032 rather than 0.045). Down-weighting the trawl indices (by

adding process error CV of 20%) reduced the magnitude of the normalised residuals and raised the median estimate of 2014 stock status from 14 to 16% B_0 (Table 9). Giving the 1989–91 spawning age frequencies a selectivity improved the fit to younger age fish, decreased the estimate of B_0 from 95 000 t to 91 000 t and increased estimated stock status from 14 to 17% B_0 (Table 9). The reduction in the mean of the acoustic q from 0.6 to 0.4 increased the median estimate of stock status to 19% B_0 , but the median estimate was still below the soft limit (Table 9). The two “bounding runs” where M and the mean of the acoustic q were shifted by 20%, still had median estimates under the soft limit, with the “LowM-Highq” run at the hard limit (Table 9). Other sensitivities not reported here included several where the effective sample size on age frequencies was appreciably increased or decreased; in all cases, this had little impact on the estimates of stock status.

Table 9: MCMC estimates of virgin biomass (B_0) and stock status (B2014 as % B_0) for the base model, and the six following sensitivity runs: a) estimating natural mortality; b) down-weighting the trawl indices by adding 20% process error to the CV; c) adding a selectivity to spawning age frequencies for 1989–91; d) reducing the mean acoustic catchability coefficient, q , from 0.6 to 0.4; e) decreasing M and increasing acoustic q by 20%; and f) increasing M and decreasing acoustic q by 20%.

Assessment	M	B_0 (000 t)	95% CI	B2014 (% B_0)	95% CI
Base model	0.045	95	87–104	14	9–21
a) Estimate M	0.032	104	96–112	11	7–16
b) Down-weight trawl	0.045	97	88–108	16	11–22
c) Spawn AF selectivity	0.045	91	83–102	17	12–24
d) Mean aco. $q = 0.4$	0.045	100	92–112	19	13–26
e) LowM-Highq	0.036	96	90–103	10	7–15
f) HighM-Lowq	0.054	99	89–114	19	13–27

The estimated fishery selectivities showed the northern fishery taking fish over 30 years with the southern fishery primarily taking fish from 20–40 years (Figure 14). The trawl-survey selectivity primarily sampled fish from 10–70 years with peak selection from 20–30 years (Figure 14). The 2010 age frequency appears to have been a subset of spawning fish focussed on those from about 50–90 years (Figure 14).

Figure 14: Base, MCMC estimated selectivities (northern and southern fisheries, the trawl survey, and the 2010 age frequency). The box at each age covers 50% of the distribution and the whiskers extend to 95% of the distribution.

The estimated YCS show strong variation across cohorts and exhibit a long-term trend, with recruitment well below average since the early 1970s (Figure 15). The most recent 10 years of estimates, 1986–1995 (those resampled for short-term projections) are well below average.

Figure 15: Base, MCMC estimated “true” YCS (R_y/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

The stock status trajectory shows an increasing trend before the start of fishery as the above average recruitment estimated by the model feeds into the spawning biomass (Figure 16). Then there is a steep decline from the start of fishery until the year 2000 when the biomass reached 10% B_0 , after which there was a slow increase (Figure 16).

Figure 16: Base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The hard limit, 10% B_0 (red), soft limit, 20% B_0 (blue), and biomass target range, 30–40% B_0 (green) are marked by horizontal lines.

ORANGE ROUGHY (ORH 2A, 2B, 3A)

Fishing intensity was estimated in each year for each MCMC sample to produce a posterior distribution for fishing intensity in each year. Fishing intensity is represented in terms of the median exploitation rate and the Equilibrium Stock Depletion (ESD). For the latter, a fishing intensity of $U_{x\%B_0}$ means that fishing (forever) at that intensity will cause the SSB to reach deterministic equilibrium at $x\%$ B_0 (e.g., fishing at $U_{30\%B_0}$ drives the SSB to a deterministic equilibrium of 30% B_0). Fishing intensity in these units is plotted as 100–ESD so that fishing intensity ranges from 0 ($U_{100\%B_0}$) up to 100 ($U_{0\%B_0}$).

Estimated fishing intensity was above the target range ($U_{30\%B_0}$ – $U_{40\%B_0}$) from 1984 to 2012 (Figure 17). In the last two years, fishing intensity has decreased to within the target range.

Figure 17: Base, MCMC estimated fishing-intensity trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The fishing-intensity range associated with the biomass target of 30–40% B_0 is marked by horizontal lines.

Biological reference points, management targets and yield

MCMC estimates of deterministic B_{MSY} and associated values were produced for the base model. The yield at 35% B_0 (the mid-point of the target range) was also estimated. There is little variation in the reference points and associated values across the MCMC samples (Table 10).

There are several reasons why deterministic B_{MSY} is not a suitable target for use in fisheries management. First, it assumes a harvest strategy that is unrealistic in that it involves perfect knowledge (current biomass must be known exactly in order to calculate the target catch) and annual changes in TACC (which are unlikely to happen in New Zealand and not desirable for most stakeholders). Second, it assumes perfect knowledge of the stock-recruit relationship, which is often poorly known. Third, it would be very difficult with such a low biomass target to avoid the biomass occasionally falling below 20% B_0 , the default soft limit according to the Harvest Strategy Standard.

Table 10: Base, MCMC estimates of deterministic equilibrium spawning stock biomass (SSB) and long-term yield (% B_0 and tonnes) for U_{MSY} and $U_{35\%B_0}$. The equilibrium SSB at U_{MSY} is deterministic B_{MSY} and the yield is deterministic MSY.

Fishing intensity		SSB (% B_0)	Yield (% B_0)	Yield (t)
U_{MSY}	Median	22.5	2.3	2214
	95% CI	21.8–23.0	2.3–2.4	2048–2415
$U_{35\%B_0}$	Median	35.0	2.2	2075
	95% CI	35.0–35.0	2.2–2.2	1916–2264

Projections

Five year projections were conducted (with resampling from the last 10 estimated YCS) for catch at the current catch limit of 930 t (with a 5% catch over-run assumed). Projections were done just for the base model. At the current catch limit (930 t), SSB is predicted to increase slowly over the next five years but still be well below the soft limit in 2019 (Figure 18). The estimated minimum time to rebuild (assuming zero catch and requiring a 70% probability of being above the lower bound of the 30–40% B_0 target range), is 21 years (T_{min}) (Figure 19).

Figure 18: Base, MCMC projections. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. An annual catch at the current catch limit of 930 t was assumed (with a 5% catch over-run in each year). The target range (30–40% B_0) is indicated by horizontal green lines, with the soft limit (20% B_0) in blue and the hard limit (10% B_0) in red.

Figure 19: Base, MCMC projections. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The annual catch used in these projections is zero tonnes. The target range (30–40% B_0) is indicated by horizontal green lines, with the soft limit (20% B_0) in blue and the hard limit (10% B_0) in red.

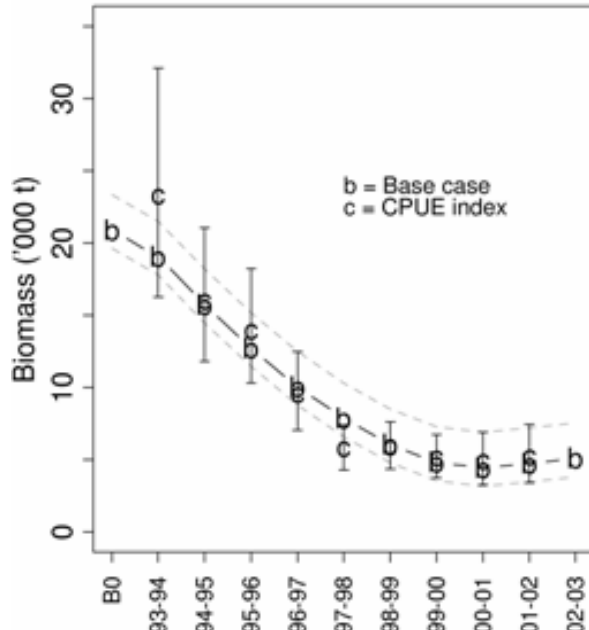

5. STATUS OF THE STOCKS

Stock Structure Assumptions

Orange roughy in ORH 2A, 2B and 3A are treated as two biological stocks based on the location of spawning grounds. These stocks are managed and assessed separately however some mixing has been shown to occur. The 2A North stock spawns around the East Cape hills off of the North Island. The 2A South, 2B and 3A stock is assumed to spawn on the Ritchie Bank.

For orange roughy stocks, the current management target is a biomass range from 30–40% B_0 .

• ORH East Cape Stock (2A North)

Stock Status	
Year of Most Recent Assessment	2003
Assessment Runs Presented	A base case with one alternative
Reference Points	Management Target: 30% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold:-
Status in relation to Target	B_{2003} was 24% B_0 , which was Unlikely (< 40%) to be at or above the target.
Status in relation to Limits	B_{2003} was Unlikely (< 40%) to be below the Soft Limit, and Very Unlikely (< 10%) to be below the Hard Limit
Historical Stock Status Trajectory and Current Status	
 <p>Estimated biomass trajectory for the base model run for the EC stock. Annual biomass estimates are mean posterior density (MPD) values and 95% confidence intervals (grey dashed lines) are calculated from the posterior profile distribution of B_0 estimates. The CPUE index CVs (sampling error plus process error) are shown.</p>	
Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass declined in the early 1990s but appeared to stabilise at around 5000 t.
Recent Trend in Fishing Mortality or Proxy	F has declined along with the agreed catch limit and remains stable at the current catch level of 200 t.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis (2003)	
Stock Projections or Prognosis	The estimated CAY (370 t) and MAY (410 t) were both greater than the catch limit of 200 t, and this suggested the stock would start to rebuild.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unlikely (< 40%) Hard Limit: Very Unlikely (< 10%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	-

Assessment Methodology and Evaluation		
Assessment Type	Type 1 - Quantitative stock assessment	
Assessment Method	Statistical catch-at-age model implemented in CASAL with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2003	Next assessment: Unknown
Overall assessment quality rank	-	
Main data inputs	- Catch data - Standardised CPUE data - 1994–95 ORH egg survey	
Data not used (rank)	-	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	-	

Qualifying Comments
The most recent assessment (2003) is now 11 years out-of-date. In recent years, the ability of stock assessment models that assume deterministic recruitment for orange roughy stocks to reflect current or projected stock status has been called into question.

Fishery Interactions
The main bycatch species are cardinalfish and alfonsino. Low productivity bycatch species include deepwater sharks, deepsea skates and corals. Protected species bycatch includes seabirds and corals.

• **ORH Mid-East Coast Stock (2A South, 2B, 3A)**

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	Base model only
Reference Points	Management Target: Biomass range 30–40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Fishing intensity range $U_{30\%B_0}$ – $U_{40\%B_0}$
Status in relation to Target	B_{2014} was estimated to be 14% B_0 Very Unlikely (< 10%) to be at or above the lower end of the management target range
Status in relation to Limits	B_{2014} is Likely (> 60%) to be below the Soft Limit B_{2014} is Unlikely (< 40%) to be below the Hard Limit
Status in relation to Overfishing	Fishing intensity in 2014 was estimated at $U_{35\%B_0}$ Overfishing is About as Likely as Not (40–60%) to be occurring

Historical Stock Status Trajectory and Current Status

Historical trajectory of spawning biomass (%B₀), median exploitation rate (%) and fishing intensity (100-ESD) (base model, medians of the marginal posteriors). The biomass target range of 30–40% B₀ and the corresponding exploitation rate (fishing intensity) range are marked in green. The soft limit (20% B₀) is marked in blue and the hard limit (10% B₀) in red. Note that the Y-axis is non-linear.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Estimated spawning biomass has been slowly increasing since about 2000.
Recent Trend in Fishing Intensity or Proxy	Estimated fishing intensity has been declining in recent years.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	At the current catch limit, the stock is projected to increase slowly over the next 5 years but still be below the soft limit in 2019. The minimum rebuild period to reach 30% B ₀ with 70% probability is estimated to be 21 years with no catch.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	For the current catch and catch limit (in the short term): Soft Limit: Very Likely (> 90%) Hard Limit: Unlikely (< 40%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	For the current catch and catch limit: As Likely as Not (40–60%)

Assessment Methodology and Evaluation

Assessment Type	Level 1 - Full quantitative stock assessment
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions

Assessment Dates	Latest assessment: 2014	Next assessment: 2022
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Acoustic biomass estimate (2013) - Trawl-survey biomass indices (1992–94, 2010), age frequencies (1993, 2010), length frequencies (1992, 1994), proportion spawning at age (1993, 2010) - Spawning-season age frequencies (1989–91, 2010) - Commercial length-frequencies (1989–90 to 2009–10) 	<ul style="list-style-type: none"> 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	<ul style="list-style-type: none"> - CPUE indices - 2002 spawning-season age frequency - Wide-area acoustic estimates - Egg survey estimates 	<ul style="list-style-type: none"> 3 – Low Quality (unlikely to be indexing stock-wide abundance) 2 – Mixed Quality (needs to be re-aged) 2 – Mixed Quality (too much potential bias due to target identification and mixed species issues) 2 – Mixed Quality (too much potential bias due to survey design assumptions not being met)
Changes to Model Structure and Assumptions	A more stringent data quality threshold was imposed on data inputs (e.g., wide-area acoustics, egg survey, and CPUE indices not used).	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - The proportion of the spawning stock biomass that was indexed by the 2013 acoustic survey (little survey effort has been expended in this area relative to other orange roughy grounds). - Patterns in year class strengths are based on only 5 years of age composition data. 	

Qualifying Comments

Estimates of stock biomass are sensitive to the means of the q priors. In addition, when higher CVs were used for the informed acoustic q priors, the median estimates of biomass and stock status were slightly higher and the confidence intervals were wider with a much higher upper bound.

Fishery Interactions

Fish bycatch is estimated to make up about 20% of the total catch in this fishery. The main bycatch species are alfonso, smooth oreo and hoki. Low productivity bycatch species include deepwater sharks, deepsea skates and corals. Observed incidental captures of protected species include corals and small numbers of seabirds.

ORANGE ROUGHY, CHATHAM RISE AND SOUTHERN NEW ZEALAND (ORH 3B)

1. FISHERY SUMMARY

1.1 Commercial fisheries

Orange roughy are found in waters deeper than 750 m throughout Quota Management Area 3B. Historically, the main fishery has been concentrated on the Chatham Rise. Annual reported orange roughy catches in ORH 3B ranged between 24 000–33 000 t in the 1980s, progressively decreased from 1989–90 to 1995–96 because of a series of TACC reductions, were stable over the mid-1990s–mid-2000s and decreased further from 2005–2006 as TACCs were further reduced (Table 1 and Figure 1).

Table 1: Annual reported catches and TACCs of orange roughy from ORH 3B. (Catches from 1978–79 to 1985–86 are from Robertson & Mace 1988) and from 1986–87 to 2016–17 from Fisheries Statistics Unit and Quota Monitoring System data). ‡

† Catches for 1979–80 to 1981–82 are for an April–March fishing year.

* Catches for 1982–83 and 1983–84 are 15 month totals to accommodate the change over from an April–March fishing year to an October–September fishing year. The TACC for the interim season, March to September 1983, was 16 125 t.

‡ Catches from 1984–85 onwards are for a 1 October–30 September fishing year.

β Agreed, non-regulatory catch limits between industry and MPI, which includes ‘shelving’ (an agreement that transfers ACE to a third party to effectively reduce the catch without adjusting the TACC).

There have been major changes in the distribution of catch and effort over the history of this fishery (Table 2). Initially, it was confined to the Chatham Rise and, until 1982, most of the catch was taken from areas of relatively flat bottom on the northern slopes of the Rise (in the Spawning Box), between mid-June and mid-August, when the fish form large aggregations for spawning (Figure 2).

ORANGE ROUGHY (ORH 3B)

From 1983 to 1989 about one third of the catch was taken from the south and east Chatham Rise, where new fishing grounds developed on and around knolls and hill features. Much of the catch from these areas was taken outside the spawning season as the fishery extended to most months of the year.

Figure 1: Reported commercial landings and TACCs for ORH 3B.

Table 2: ORH 3B catches by area, to the nearest 10 t or 100 t, and by percentage (to the nearest percent) of the total ORH 3B reported catch. Catches are equivalent to those shown in Table 1, but allocated to area using the ratio of estimated catches, and revised such that all years are from 1 October–30 September. Note that catches for the East Rise are given by the sum of Spawning Box and Rest of East Rise.

In the early 1990s, effort within the Chatham Rise further shifted from the Spawning Box to eastern and northwestern parts of the Rise. The Spawning Box was closed to fishing from 1992–93 to 1994–

95. In more recent years, catches from the main fishing grounds on the Chatham Rise have declined due to TACC reductions.

The early 1990s also saw the Puysegur fishery develop, followed by other fishing grounds near the Auckland Islands and on the Pukaki Rise, which was also a focus for the fishery south of the Chatham Rise.

Since 1992–93, the distribution of the catch within ORH 3B has been affected by a series of catch-limit agreements between the fishing industry and the Minister responsible for fisheries. Initially, the agreement was that at least 5 000 t be caught south of 46° S. Subsequently, the catch limits, and the designated sub-areas to which they apply, have changed from year to year.

The TACC was reduced to 3 600 t in 2011–12 (Table 1). The agreed catch limit for the East and South Chatham Rise is currently 3 100 t (Table 3). A three-year staged process to reduce F to F_{MSY} was initiated on 1 October 2008. Under this approach, the catch limit was to be set at 4.5% ($F_{MSY} = M$) of the estimated current biomass in each year from 1 October 2010. However, for 2013–14 the TACC was increased to 4500 t (Table 1) in response to the increased biomass estimates following the discovery of the Rekohu plume.

The catch limit for the Sub-Antarctic has been substantially undercaught since 2009–10. However, the combined East and South Rise sub-area catch limits were exceeded by 450 t in 2005–06 and by 350 t in 2006–07 (100 t were taken against the allowance for research surveys). Taking the research allowance into account, catch limits for the combined east and south Rise sub-area have not been exceeded in subsequent years. Since 2004–05, 250 t of the ORH 3B TACC has been set aside for industry research surveys (Table 3), although this has sometimes been used in areas outside the East and South Chatham Rise.

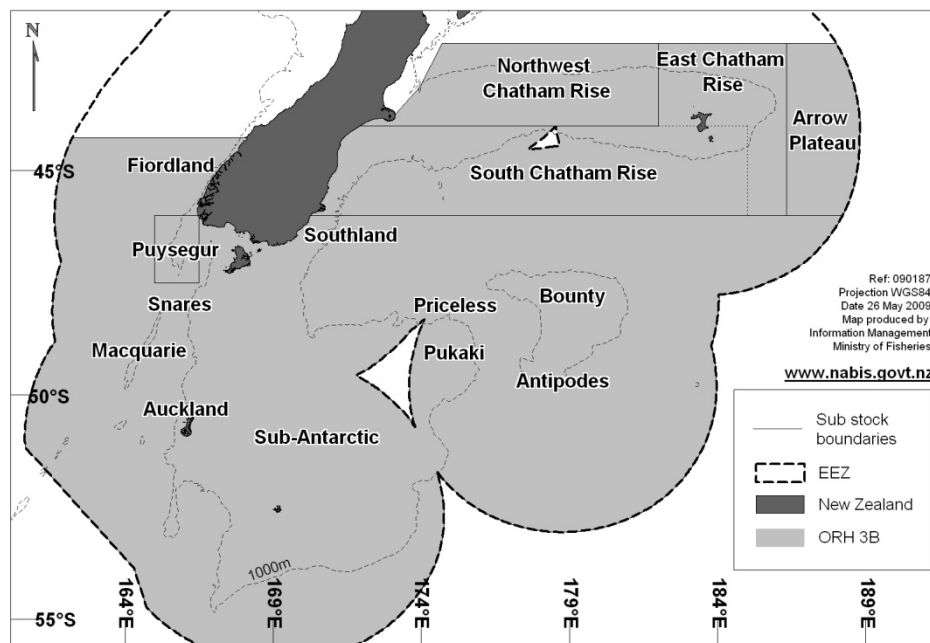

Figure 2: ORH 3B sub-areas and the approximate position of other named fisheries outside of the Chatham Rise. The Spawning Box is in the western part of the East Rise (to the west of the vertical broken line at 175°W). The East and South Rise are currently managed as a single unit. The Arrow Plateau has been designated a Benthic Protected Area. The Sub-Antarctic is all areas below 46°S on the east coast, and 44°16'S on the west coast, except Puysegur.

ORANGE ROUGHY (ORH 3B)

Table 3: Catch limits (t) by designated sub-area within ORH 3B, as agreed between the industry and the Ministers responsible for fisheries since 1992–93. Note that East Rise includes the Spawning Box, closed between 1992–93 and 1994–95. Sub-area boundaries have varied somewhat between years. * South Rise included in East Rise catch limit. ** Arrow Plateau included in Sub-Antarctic.

† an additional 250 t set aside for industry research surveys.

‡ 8650 t allocated to the East and South Chatham Rise combined, with no more than 2000 t from the South Rise, and no more than 7250 t from the East Rise.

Combined East and South Rise catch not to exceed 7650 t; East Rise not to exceed 6500 t; South Rise catch not to exceed 1750 t.

§ In 2008–09, the catch from the spawning plume was not to exceed 3285 t.

β From 2010–11 to 2012–13, quota owners agreed to avoid fishing the Northwest Rise.

δ Quota owners agreed to shelve 207 tonnes of Northwest Chatham Rise ACE for 2014–15 to 2017–18. This left 1043 tonnes available to catch.

Outside the Spawning Box, catches increased in the 1990s and catch rates have been highly variable, sustained largely by the discovery of new fishing areas. Flat areas on the Northwest Rise and several major hills on the South Rise were important in the late 1980s, but currently do not support their previous levels of catch, now accounting for less than 5% of the estimated catch (Table 4). High catch rates can still occur, but these are less frequent than observed in the early years of the fishery. Catches from the Northwest Rise fell to near zero in 2010–11 as a result of an agreement among quota owners to avoid fishing in this area (Table 2). This agreement was extended to the 2011–12 and 2012–13 fishing years. Quota owners then agreed to shelve 207 tonnes of Northwest Chatham Rise ACE for 2014–15 to 2017–18.

Between 1991–92 and 2000–01, more than half of the Chatham Rise catch came from four hill complexes: the Andes, Smith City and neighbours, Graveyard, and Big Chief and neighbours (Table 4). All of these have shown a decline in unstandardised catch rate since the early years of the fishery, and in recent years, catch rates in these hill complexes have remained relatively low. After 2000–01, the proportion of the catch from these hill complexes decreased, as a greater proportion of the catch came from the Spawning Box (about 39% in 2008–09). In addition, large catches have been made in recent years outside of the spawning season, in recently developed areas of the southeast Rise. Catches from the Spawning Box taken during the spawning season (which peaks in July) have been relatively high since 2001–02, although unstandardised catch rates have been variable (Table 4).

Table 4: Orange roughy estimated catches (to nearest 10 t) and unstandardised median catch rates (to nearest 0.1 t/tow) for four important hill complexes and the Spawning Box In season (spawning plume area, May-August) and Out season (September-April) on the Chatham Rise (letters indicating subareas, as in Table 3, in parentheses), using catch and effort data held by NIWA. Only tows targeted at orange roughy are included. (Approximate positions are: Big Chief, 44.7 S, 175.2 W; Smiths City and near-neighbours, 43.1 S, 174.2 W; Andes, 44.2 S, 174.6 W; Graveyard, 42.8 S, 180 W). -, catch < 10 t (2016–17 data are provisional, and catch totals are possibly incomplete). - means catch < 10 t. NA means catch > 10 t but there were fewer than 3 vessels in the fishery.

Table 5: Estimated ORH 3B catches (to the nearest 10 t) and unstandardised median catch rates (to nearest 0.1 t/tow) for areas outside the Chatham Rise, using estimated catch and effort data held by NIWA. Only tows targeted at orange roughy are included. For this table the areas were defined by the following rectangles: Arrow - 42.17–46°S, 173.67°W; Auckland - 49–52°S, 165–167°E; Bounty - 46–47.5°S, 177.5–180°E; Priceless - 48–48.44°S, 174.7–175.2°E; Other Pukaki - 47–50.4°S, 174–176.4°E (and not in Priceless); Puysegur - 46–47.5°S, 165–166.5°E. The area described as Antipodes in previous reports is now included in Other Pukaki. All years are from 1 October–30 September (2016–17 data are provisional and catch totals may be incomplete). - means catch < 10 t. N/A means catch greater than 10 t, but there were fewer than 3 vessels in the fishery.

The first fishery to be developed south of the Chatham Rise was on Puysegur Bank, where spawning aggregations of orange roughy were found during a joint Industry-Ministry exploratory fishing survey in 1990–91. The fishery developed rapidly, but from 1993–94 catch limits were substantially under-caught. Catch limits were subsequently reduced from the initial level of 5 000 t, and the industry implemented a catch limit of 0 t beginning in the 1997–98 fishing year (reported catches in 2004–05 and 2005–06 were taken during industry surveys). A catch limit of 150 t was provided for research purposes in Puysegur from 2010–11 (Table 3). Following a stock assessment of Puysegur in 2017, a commercial catch limit was set at 347 t from 1 October 2017.

Exploratory fishing on the Macquarie Ridge south of Puysegur in 1993 led to the development of a fishery off the Auckland Islands. Total catch rose to around 900 t in 1994–95, but then dropped to less than 200 t by 1999–00, and catches remained low until an increase in 2013–14. In 1993–94, catches were taken on the ‘Arrow Plateau’, and became the first major fishery to develop on the easternmost section of the Chatham Rise. A catch limit of 3 000 t was put in place for 1994–95, with an additional limit of 500 t for each hill. Only a few hills in this area have been fished successfully, and the catch has never reached the catch limit, which was reduced to 1 000 t by the early 2000s (Table 3). The Arrow Plateau was closed to orange roughy fishing when it was designated a Benthic Protected Area in 2007 (Table 5).

In 1995–96, large catches were reported on the southeast Pukaki Rise, with a catch total of over 3 000 t. However, the catches dropped rapidly and the fishery effectively ceased within a few years. From 2001–02, a fishery developed on the northeast Pukaki Rise, including the area known as Priceless, where catches were mostly taken at the start of the fishing year. Catches at Priceless reached the feature limit of 500 t for each of the six years up to 2006–07, but catches and catch rates declined substantially from 2007–08, and have remained low since. Areas of the northeast Pukaki Rise outside of Priceless were developed in 2004–05 and also showed a rapid decline in catches and catch rates. By 2007–08, the fishery in the sub-Antarctic was limited to the Auckland Islands and northeast Pukaki Rise areas. From 2008–09 the fishery extended over a relatively wide area, but catches and catch rates were low, and the fishery effectively ceased from 2010–11 (Table 5).

Catches of orange roughy have also been taken off the Bounty Islands (around 100–200 t per year from 1997–98 to 2004–05, but infrequently since then, and none since 2011–12) (Table 5), off the Snares Islands (up to around 500 t per year, but infrequently in recent years), areas of the Macquarie Ridge (100–500 t per year from 2000–01 to 2004–05, and in 2008–09), and off Fiordland (around 500 t in 2000–01, but subsequent catches rapidly decreased).

1.2 Recreational fisheries

No recreational fishing for orange roughy is known in this quota management area.

1.3 Customary non-commercial fisheries

No customary non-commercial fishing for orange roughy is known in this quota management area.

1.4 Illegal catch

No information is available on illegal catch in this quota management area.

1.5 Other sources of mortality

There has been a history of catch overruns on the Chatham Rise because of lost fish and discards, and discrepancies in tray weights and conversion factors. In assessments, total removals from each part of the Chatham Rise were assumed to exceed reported catches by the overrun percentages in Table 6. For Puysegur and other southern fisheries there is no reason to believe that, if there was an overrun in catches, this shows any trend over time. For this reason, it was assumed that there was no overrun for this area.

Table 6: Chatham Rise catch overruns (%) by year.

Year	1978–79	1979–80	1980–81	1981–82	1982–83	1983–84	1984–85	1985–86	1986–87	1987–88
Overrun	30	30	30	30	30	30	30	28	26	24
Year	1988–89	1989–90	1990–91	1991–92	1992–93	1993–94	1994–95 and subsequently			
Overrun	22	20	15	10	10	10	5			

Within the TAC an allowance of 5% of the TACC is allocated for other sources of mortality (currently 225 t).

2. BIOLOGY

Biological parameters used in this assessment are presented in the Biology section at the beginning of the Orange Roughy section.

3. STOCKS AND AREAS

For the purposes of this report the term “stock” refers to a biological unit with a single major spawning ground, in contrast to a “Fishstock” which refers to a management unit.

Genetically two main stocks are recognised within ORH 3B (Chatham Rise and Puysegur; Smith & Benson 1997) and these are considered to be distinct from stocks in adjacent areas (Cook Canyon and Ritchie Bank). However, it is likely, because of their geographical separation and discontinuities in the distribution of orange roughy, that concentrations of spawning fish on the Arrow Plateau, near the Auckland Islands, and west of the Antipodes Islands also form separate stocks.

Genetic data have been applied to define stock boundaries, both within ORH 3B, and between it and adjacent areas. Mitochondrial DNA shows that there are considerable differences between Puysegur fish and fish from the geographically adjacent areas Cook Canyon and Chatham Rise. Allozyme frequency studies suggest that Chatham Rise fish are distinct from those on the Ritchie Bank (ORH 2A). These data also suggest multiple stocks within the Chatham Rise, but do not indicate clear stock boundaries. Although there is significant heterogeneity amongst allozyme frequencies from different areas of the Rise, these frequencies varied as much in time (samples from the same location at different times) as in space (samples from different locations at the same time).

Chatham Rise

The stock structure of orange roughy on the Chatham Rise was comprehensively reviewed in 2008 (Dunn & Devine 2010). This review evaluated all available data as no single dataset seemed to provide definitive information about likely stock boundaries. The data analysed included: catch distribution and CPUE patterns; location of spawning and nursery grounds; inferred migrations; size, maturity and condition data; genetic studies, and habitat and natural boundaries.

There is evidence that a separate stock exists on the Northwest Rise. The Northwest Rise contains a large spawning ground on the Graveyard Hills, and also nursery grounds around, and primarily to the west of, the Graveyard Hills. There is a gap in the distribution of early juveniles (under 15 cm SL)

between the Graveyard area and the Spawning Box at approximately 178°W. A research trawl survey found post-spawning adult fish to the west, but not to the east, of the Graveyard Hills, and a westerly post-spawning migration was inferred. Analyses of median length from commercial and research trawls found that orange roughy on the Northwest Chatham Rise and Graveyard Hills were smaller than those on the East Rise. A substantial decline in the size of 50% maturity after 1992 was found for both the Graveyard Hills and the Northwest Rise, but not for other areas. The only information that does not support the Northwest Rise being a separate stock is an indication from patterns in commercial catch rates that some fish arriving to spawn in the Spawning Box may come from the west (Coburn & Doonan 1994, 1997). Catch data and genetic studies do not shed any further light on stock structure. Oceanographic models suggest that a gyre to the east of the Graveyard may provide a mechanism for a separation between the Northwest Chatham Rise and the East Rise. Based on the available data, the Northwest Chatham Rise is considered to be a separate stock.

The separation of the Northeast Hills and Andes as separate stocks from the Spawning Box and Eastern Flats was based on observations of simultaneous spawning aggregations occurring on these hills, and because stock assessment models indicated a mismatch between the standardised CPUE trends. On the other hand, the occurrence of a continuous nursery ground throughout the area; similar trends in size of 50% maturity in each area; the essentially continuous habitat with similar environmental conditions and inferred post-spawning migrations from the Spawning Box towards the east Rise all suggest that all of these areas are a single stock. Analyses of median lengths from commercial catches showed no obvious differences between areas. In addition, the spawning aggregations found on the Northeast Hills and Andes appear to have been minor compared to that in the Spawning Box. The spawning aggregation on the Northeast Hills is also associated with an increase in mean length and catch rates, suggesting that fish spawning on these hills are not resident, and thus are not separate from the surrounding area. Based on the available data the Northeast Hills and Andes are therefore considered to be from the same stock as the Spawning Box and Eastern Flats.

The only evidence to separate the eastern area of the South Rise (Big Chief and surrounds) from the East Rise is the lack of spawning migrations inferred from an absence of a seasonal effect in standardised CPUE analyses. The evidence that the Big Chief area is the same stock as the East Rise includes the fact that the nursery grounds and habitat are continuous; there were no splits between the areas identified from analyses of median length; and the fisheries are similar. The reports of spawning fish around Big Chief have been infrequent, and so are considered equivocal on stock structure. The Big Chief area is therefore considered part of the East Rise stock.

There is weak evidence that the area of the South Rise west of and including Hegerville is a separate stock. The evidence includes median length analyses which indicated a split in this area, and an oceanographic front at 177°W. However, very few catches of spawning orange roughy have been reported in this area, and there appears to be no substantial nursery ground. Both of these factors support the idea that this area does not have a separate stock. In the area to the west of the suggested split the fish are relatively small during spawning, and relatively large during non-spawning. Combined with a standardised CPUE which shows a decline in abundance around July (peak spawning), and a somatic condition factor which declines during September–November (post-spawning), this supports a hypothesis of adult fish leaving the area to spawn elsewhere.

The South Rise could provide feeding habitat for the stock, which is estimated to have had an initial biomass of over 300 000 t, an amount that was probably too large to inhabit only the East Rise. There is more evidence to support orange roughy in this area being part of the East Rise stock than there is to the contrary. The current hypothesis is that the area to the west of the current convergence may be relatively marginal habitat, where larger juvenile, maturing and adult orange roughy were once predominant, and there is little spawning and few juveniles because the water is relatively cold.

Based on these analyses, the Chatham Rise has been divided into two areas: the Northwest, and the East and South Rise combined (Figure 2). The centre of the Northwest stock is the Graveyard Hills. The centre of the East and South Rise stock is the Spawning Box during spawning, and the southeast corner of the Rise during non-spawning.

4. STOCK ASSESSMENT

No model-based stock assessments were conducted for ORH 3B stocks from 2007 to 2013 inclusive. This was primarily because the 2006 stock assessment, which assumed deterministic recruitment, showed an increasing trend in biomass which was not supported by recent biomass indices. Deterministic recruitment was assumed because ageing data were considered to be unreliable. With the successful assessment of the MEC stock in 2013, which used age data from the new ageing methodology (Tracey et al 2007; Horn et al 2016), there was a return to model-based assessment in 2014. Recruitment in all of these assessments has been derived from limited age data.

4.1 Northwest Chatham Rise

A Bayesian stock assessment was conducted for the Northwest Chatham Rise (NWCR) stock in 2018, using data up to 2016–17. This used an age-structured population model fitted to acoustic-survey estimates of spawning biomass, proportion-at-age from a trawl survey and targeted trawling on a spawning aggregation, proportion-spawning-at-age from a trawl survey, and length frequencies from the commercial fishery.

4.1.1 Model structure

The model was single-sex and age-structured (1–100 years with a plus group), with maturity estimated separately (i.e., fish were classified by age and as mature or immature). A single-time step was used and the single fishery was assumed to be year-round on mature fish. Spawning was taken to occur after 75% of the mortality and 100% of mature fish were assumed to spawn each year. The catch history was constructed from the Northwest catches in Table 2 using the catch over-run percentages in Table 6. Natural mortality was assumed to be fixed at 0.045 and the stock-recruitment relationship was assumed to follow a Beverton-Holt function with steepness of 0.75. The remaining fixed biological parameters are given in table 2 of the Orange Roughy Introduction section.

4.1.2 Input data and statistical assumptions

There were three main data sources for observations fitted in the assessment: acoustic-survey spawning biomass estimates from the main spawning hills (Graveyard and Morgue); an age frequency and an estimate of proportion-spawning-at-age taken from a 1994 wide-area trawl survey; an age-frequency taken from targeted trawls above Morgue, and length frequencies collected from the commercial fishery covering 1989–2005.

Acoustic estimates

Three types of acoustic-survey estimates were available for use in the assessment: AOS estimates (from a multi-frequency towed system, e.g., see Kloser et al 2011); 38 kHz estimates from a towed-body system; and 38 kHz estimates from a hull-mounted system. The reliability of the data from the different systems in each year was considered and estimates from the AOS and towed-body systems were used in the base model (Table 7). An alternative treatment of the available acoustic data was to include additional survey estimates from 2002 and 2004 (Table 7). All of the data in Table 7 were used in the sensitivity run labelled “Extra acoustics”.

Table 7: Acoustic survey estimates of spawning biomass used in the base model (excludes 2002 and 2004) and the sensitivity run “Extra acoustics” (uses all data). “GY” = Graveyard, “M” = Morgue, “O” = other hills. The CVs are those used in the model and do not include any process error.

Year	System	Frequency	Areas	Snapshots	Estimate (t)	CV (%)
1999	Towed-body	38 kHz	GY+M+O	1	8 126	22
2002	Towed-body	38 kHz	GY+O	2	9 414	20
2004	Hill-mounted	38 kHz	GY	6	2 717	16
2012	AOS	38 kHz	GY	3	5 550	17
	AOS	38 kHz	M	4	9 087	11
2013	AOS	120 kHz	GY	1	6 656	31
2016	AOS	38 kHz	GY	1	0	N/A
	AOS	38 kHz	M	3	14 051	13

The acoustic estimates in 1999, 2012 (total = 14 637 t, CV 17%), and 2016, were assumed to represent “most” of the spawning biomass in each year. This was modelled by treating the acoustic estimates as relative biomass and estimating the proportionality constant (q) with an informed prior. The prior was normally distributed with a mean of 0.8 (i.e., “most” = 80%) and a CV of 19% (see Orange Roughy Introduction). The 2013 Graveyard estimate was modelled as relative biomass with an informed prior on the q with a mean of 0.3 (derived from the relative proportions of the Graveyard and Morgue estimates in 2012 with the 80% assumption).

Trawl survey data

A wide-area trawl survey of the northwest flats was conducted in late May and early June of 1994 (72 stations; Tracey & Fenaughty 1997). An age-frequency for the trawl-selected biomass was estimated using 300 otoliths selected using the method of Doonan et al (2014). The female proportion spawning-at-age was also estimated. These data were fitted in the model: age frequency (multinomial with an effective sample size of 60); proportion-spawning-at-age (binomial with effective sample size at each age equal to the number of female otoliths at age).

Length frequencies

The length frequencies from the previous assessment in 2006 were used: nine years of length-frequency data from the period 1989–97 were combined into a single length-frequency that was centred on the 1993 fishing year. Eight years of length-frequency data from the period 1998–2005 were combined into a single length-frequency that was centred on the 2002 fishing year. The effective sample size was set at one sixth of the number of tows for each period: 19 for the “1993” period and 35 for the “2002” period (A. Hicks pers. comm.). The data were assumed to be multinomial.

Age frequencies

In addition to the age frequencies from the 1994 trawl survey, an age frequency was developed from samples taken above Morgue during the spawning season in 2016. Approximately 300 otoliths were randomly selected from three tows. The age frequency was fitted as multinomial with effective sample sizes of 60. The 2016 age frequency from Morgue was derived from the use of a demersal trawl fished a few metres off the bottom, and this in part led to concerns about the representativeness of this sampling.

4.1.3 Model runs and results

In the base model, the acoustic estimates from 1999, 2012, 2013, and 2016 were used, and the age-frequency from 2016 was excluded. There were four main sensitivity runs: add the extra acoustic data; the *LowM-Highq* and *HighM-Lowq* “standard” runs (see Orange Roughy Introduction); and including the 2016 age-frequency with its own (logistic) selectivity.

In the base model, the main parameters estimated were: virgin (unfished, equilibrium) biomass (B_0), maturity ogive, trawl-survey (logistic) selectivity, CV of length-at-mean-length-at-age for ages 1 and 100 years (linear interpolation assumed for intermediate ages), and year class strengths (YCS) from 1940 to 1979 (with the Haist parameterisation and “nearly uniform” priors on the free parameters). In the sensitivity run including the 2016 age-frequency the YCS were estimated from 1940 to 1992.

Model diagnostics

The model provided good MPD fits to the data (Figures 3 and 4). The acoustic indices, free to “move” somewhat as they are relative, were fitted well (Figure 3). The posterior estimates for the acoustic qs were not very different from the priors, but there was some movement in the Graveyard and Morgue q , with the posterior slightly lower (and therefore SSB slightly higher) than expected (Figure 5).

Numerous MPD sensitivity runs were performed. These showed that the main drivers of the estimated stock status were natural mortality (M) and the means of the acoustic q priors (lower M and higher mean q give lower stock status; higher M and lower mean q give higher stock status).

ORANGE ROUGHY (ORH 3B)

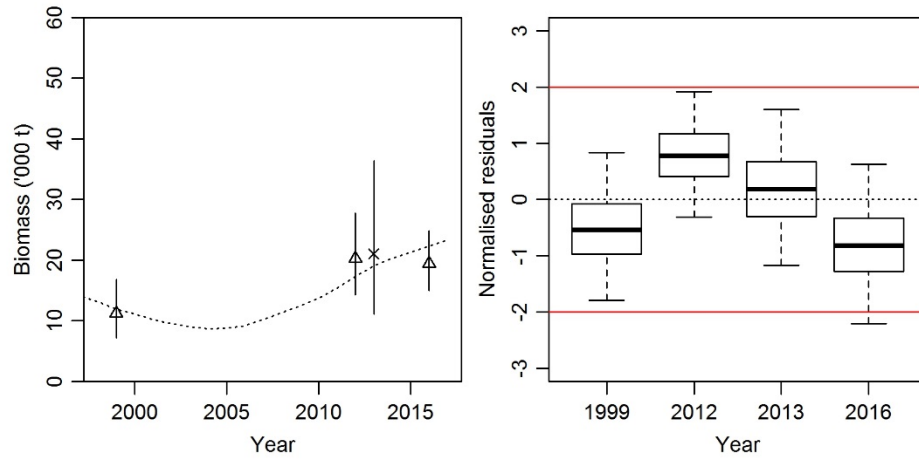

Figure 3: NWCR, base, (left) MPD fits to the acoustic biomass indices; broken line, spawning biomass trajectory; scaled acoustic indices for x, Graveyard survey, and Δ, Graveyard and Morgue surveys; (right) MCMC normalised residuals for the acoustic biomass indices. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

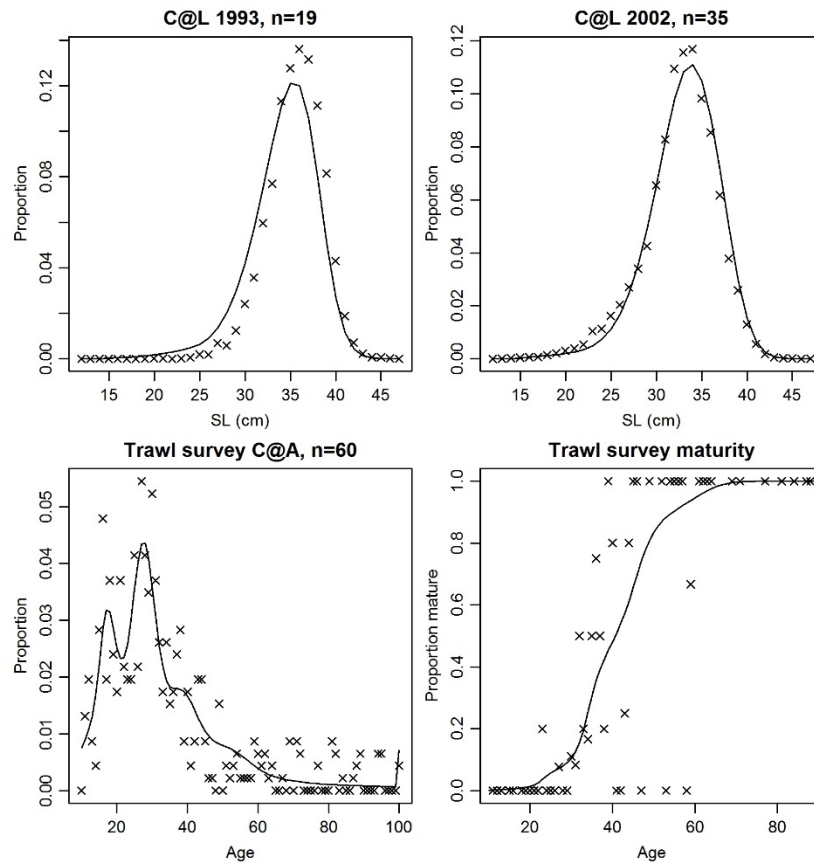

Figure 4: NWCR, base, MPD fits: (x, observations; lines, predictions): (top) commercial catch-at-length samples (n is the effective sample size); (bottom) trawl survey catch-at-age and proportion mature at age.

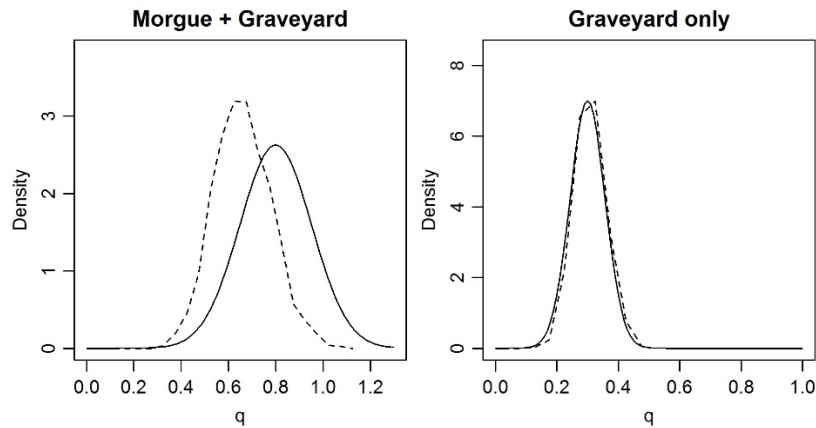

Figure 5: NWCR base, MCMC diagnostics: prior (solid line) and posterior (broken line) distributions for the two acoustic q s (left, mean q -prior = 0.8; right, mean q -prior = 0.3).

When the Morgue age-frequency was fitted assuming that the selectivity on Morgue was equal to maturity the fit was poor, particularly to the left-hand side of the age frequency distribution. When the Morgue age frequency was fitted assuming a separate logistic selectivity the fit was acceptable (Figure 6). The Morgue age frequency had an unexpectedly high proportion of older fish, and the sampling methodology was also unusual. As a result, it was agreed to exclude the Morgue age frequency data from the base model.

Figure 6: NWCR, base, MPD fits: (x, observations; lines, predictions) to the Morgue age frequency (effective sample size $n = 60$).

MCMC Results

For the base model, and the sensitivity runs, MCMC convergence diagnostics indicated no lack of convergence. Virgin biomass, B_0 , was estimated to be between 64 000–67 300 t for all runs (Table 8). Current stock status was similar across the base and the first two sensitivity runs (Table 8). For the two “bounding” runs, where M and the mean of the acoustic q priors were shifted by 20%, median current stock status was estimated to be close to the lower bound, or upper bound, of the target range of 30–50% B_0 (Table 8).

Table 8: NWCR, MCMC estimates of virgin biomass (B_0) and stock status (B_{2017} as % B_0) for the base model and four sensitivity runs.

	M	B_0 (000 t)	95% CI	B_{2017} (% B_0)	95% CI
Base	0.045	65.2	59.9–75.0	38	31–48
Extra acoustics	0.045	64.0	60.0–76.7	36	31–43
Include Morgue AF	0.045	65.1	58.6–76.5	38	30–48
Low M -High q	0.036	67.3	63.0–73.9	29	23–36
High M -Low q	0.054	65.5	58.2–77.7	48	40–58

ORANGE ROUGHY (ORH 3B)

For the base model, there was a 98% probability that the stock was above 30% B_0 in 2017. For the sensitivity runs, the probability of being above 30% B_0 in 2017 was 98% (Extra acoustics), 97% (Include Morgue AF), 36% (Low M -High q), and 100% (High M -low q).

The estimated YCS showed little variation across cohorts, but recruitment was relatively high in 1940–52, 1965–68, and 1975–79 (Figure 7).

Figure 7: NWCR base, MCMC estimated “true” YCS (R_y/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

The estimated spawning-stock biomass (SSB) trajectory showed a declining trend from 1980 (when the fishery started) through to 2004 when the biomass was About as Likely as Not (40–60%) to be below the soft limit (Figure 8). Since 2005 the estimated biomass has increased steadily.

Figure 8: NWCR base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. Dotted lines indicate the hard limit (10% B_0) and soft limit (20% B_0), dashed lines the management target range (30–50% B_0).

Fishing intensity was estimated in each year for each MCMC sample to produce a posterior distribution for fishing intensity by year. Fishing intensity is represented in term of the median exploitation rate and the Equilibrium Stock Depletion (ESD). For the latter, a fishing intensity of $U_{x\%B_0}$ means that fishing (forever) at that intensity (at that rate, not tonnage) will cause the SSB to reach deterministic equilibrium at $x\%$ B_0 (e.g., fishing at $U_{30\%B_0}$ forces the SSB to a deterministic equilibrium of 30% B_0). Fishing intensity in these units is plotted as 100–ESD so that fishing intensity ranges from 0 ($U_{100\%B_0}$) up to 100 ($U_{0\%B_0}$).

Estimated fishing intensity was above $U_{20\%B_0}$ for most of the history of the fishery; it was briefly in the target range ($U_{30\%B_0}$ – $U_{40\%B_0}$) from 2009–2010 before dropping substantially when the industry agreed

to curtail fishing the NWCR in 2011, and has been in or just below the target range since 2014 (Figure 9). There was less than a 1% probability that the exploitation rate in 2017 was below $U_{30\%B_0}$.

Figure 9: NWCR base, MCMC estimated fishing-intensity trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The fishing-intensity range associated with the biomass target of 30–50% B_0 is marked by horizontal lines.

Projections

Five-year biomass projections were made for the Base model run assuming future catches to be the TACC (1 250 t), or the current agreed catch limit (1 043 t; 207 t has been shelved). For each projection scenario, future recruitment variability was sampled from actual estimates between 1940 and 1979.

At the TACC (1 250 t) and the current agreed catch limit (1 043 t), SSB is predicted to remain stable or slowly increase over the next five years, and the probability of the SSB going below the soft or hard limits is zero (Table 9).

Table 9: ORH 3B NWCR Bayesian median and 95% credible intervals (in parentheses) of projected B_{2022} , B_{2022} as a percentage of B_0 , and B_{2022}/B_{2017} (%) for the model runs.

Model run	Catch	B_{2022}	B_{2022} (% B_0)	B_{2022}/B_{2017} (%)	$p(B_{2022} < 0.2 B_0)$	$p(B_{2022} < 0.1 B_0)$
Base	1 043	26 500 (20 000–38 100)	41 (33–51)	107 (104–111)	0	0
	1 250	25 600 (19 100–37 200)	39 (31–50)	104 (101–107)	0	0

Biological reference points, management targets and yield

Orange roughy stocks with model based stock assessments are managed according to the Harvest Control Rule (HCR) that was developed in 2014 using a Management Strategy Evaluation (MSE) (Cordue 2014b). The HCR has a target management range of 30–50% B_0 .

Yield estimates are not reported for this stock.

4.2 East and South Chatham Rise

A Bayesian stock assessment was conducted for the East and South Chatham Rise (ESCR) stock in 2018, using data up to 2016–17. The model was an age-structured population model fitted to acoustic-survey estimates of spawning biomass, trawl-survey biomass indices, age frequencies from spawning aggregations, and length frequencies from trawl surveys and commercial fisheries.

4.2.1 Model structure

The model was single-sex and age-structured (1–100 years with a plus group), with maturity estimated separately (i.e., fish were classified by age and as mature or immature). A single-time step was used and four year-round fisheries, with logistic selectivities, were modelled: Box & flats, Eastern hills, Andes, and South Rise. These fisheries were chosen following Dunn (2007) who assessed the Box & flats, Eastern hills, and Andes as separate stocks and hence had already prepared length frequency data for those fisheries. No length frequencies were available from the South Rise fishery and its selectivity was assumed to be the same as the Andes (so effectively there were three fisheries in the model). Spawning was taken to occur after 75% of the mortality and 100% of mature fish were assumed to spawn each year.

The catch history was constructed by apportioning the total ORH 3B reported catch across areas using catch proportions from estimated catch on TCEPR forms (Table 4). The over-run percentages in Table 6 were applied. Natural mortality was assumed fixed at 0.045 and the stock-recruitment relationship was assumed to follow a Beverton-Holt function with steepness of 0.75. The remaining fixed biological parameters are given in table 2 of the Orange Roughy Introduction section.

4.2.2 Input data and statistical assumptions

There were four main data sources for observations fitted in the assessment: acoustic-survey spawning biomass estimates from the Old-plume (2002–2014, 2016), Rekohu (2011–2014, 2016) and the Crack (2011, 2013, 2016); age frequencies from the spawning areas (2012, 2013, and 2016); trawl survey biomass indices and length frequencies; and length frequencies collected from the commercial fisheries.

Acoustic estimates

The Old plume was acoustically surveyed as early as 1996, but the survey estimates are only considered to represent a consistent time series from 2002–2012 (see Cordue 2008; Hampton et al 2008, 2009, 2010; Doonan et al 2012). Like the Rekohu plume, which was first noted in 2010 and first surveyed in 2011, the Old plume occurs on an area of flat bottom and can be adequately surveyed using a hull-mounted transducer. In 2011, 2013 and 2016, an additional (but known historically) spawning area was surveyed; known as the Crack (also known as Mt. Muck), it is an area of rough terrain which requires a towed-body or trawl-mounted system to be used to reduce the height of the shadow or dead zone (i.e., with the transducer at a depth of about 500–700 m).

The estimates selected by the DWFAWG for use in the stock assessment are shown in Table 10. In order to make the estimates as comparable as possible across years, only biomass estimates from 38 kHz transducers were used and those from the hull-mounted system were weather-adjusted in the same way as earlier estimates (see presentations from Kloser and Ryan to the DWFAWG meetings in 2013 and 2014).

A key question evaluated in the 2014 assessment was how long has the Rekohu plume been in existence (Cordue, 2014a). If the Rekohu plume had always existed (and was not discovered until 2010) then it would be one of three major spawning sites and could be modelled as such along with the Old plume and the Crack. This would imply that the Old-plume time series was tracking a consistent part of the spawning biomass (and its decline over time was therefore an important indicator of stock status). If, on the other hand, the Rekohu plume had very recently formed, this would imply that the Old-plume time series was a biomass index only up until the year before the Rekohu plume came into existence.

Table 10: Acoustic estimates of average pluming spawning biomass in the three main spawning areas as used in the assessment. All estimates were obtained from surveys on *FV San Wataki* from 38 kHz transducers. Each estimate is the average of a number of snapshots as reflected by the estimated CVs. Some estimates have been revised since the 2014 assessment (Dunn & Doonan, in prep.).

	Old plume		Rekohu		Crack	
	Estimate (t)	CV (%)	Estimate (t)	CV (%)	Estimate (t)	CV (%)
2002	63 950	6	—	—	—	—
2003	44 316	6	—	—	—	—
2004	44 968	8	—	—	—	—
2005	43 923	4	—	—	—	—
2006	47 450	10	—	—	—	—
2007	34 427	5	—	—	—	—
2008	31 668	8	—	—	—	—
2009	28 199	5	—	—	—	—
2010	21 205	7	—	—	—	—
2011	16 422	8	28 113	18	6 794	21
2012	19 392	7	27 121	10	—	—
2013	15 554	14	33 348	10	5 471	16
2014	19 360	18	44 421	25	—	—
2015	—	—	—	—	—	—
2016	11 192	13	27 027	13	5 341	10

Following Cordue (2014a), in the base model it is assumed that the Old-plume time series cannot be relied on to provide a consistent index for any part of the spawning biomass. In 2011, 2013 and 2016, the estimates of average spawning biomass across the three areas were summed to form comparable indices for each year. The 2012 and 2014 estimates from Rekohu and the Old-plume were summed to provide a 2012 and 2014 index with a different proportionality constant or q . The Old-plume indices from 2002–2010 were used, but each point in the time series was given its own q . Informed priors were used for all of the q s in the Old-plume series, for the 2012 and 2014 biomass indices, and the indices comprising 2011, 2013, and 2016 observations.

For 2011, 2013, and 2016, it was assumed that “most” of the biomass was being indexed so the “standard” acoustic q prior was used: lognormal (mean = 0.8, CV = 19%) (see Orange Roughy Introduction). The mean of the q prior for 2012 and 2014 was derived from the observed biomass proportions across the three areas and the assumption that 80% of the spawning biomass was indexed in 2011, 2013 and 2016, which gave a mean of 0.7 for the 2012 and 2014 indices, a reflection that this index did not include an estimate for the Crack. For 2002 to 2010 the means of the q priors were assumed to decrease linearly from 0.7 (2002) down to 0.30 (2010), reflecting the gradual increase in the relative importance of the Rekohu plume. The linear sequence was derived by assuming 0.7 in 2002 (i.e., assuming that the Rekohu plume did not exist and only the Crack was missing from the survey estimate) and using the observed biomass proportions in 2011 with the 80% assumption (which gave the Old-plume being about 25% of the total spawning biomass). To reflect the increased uncertainty in the acoustic q s in years other than 2011 and 2013, the priors were given an increased CV of 30%.

A sensitivity run was conducted that, similar to the base run, assumed for 2011, 2013, and 2016, the “standard” acoustic q prior: lognormal (mean = 0.8, CV = 19%). However, the q for the 2012 and 2014 surveys was estimated with a uniform prior, but with a penalty on the ratio between the q estimated for the 2011, 2013, and 2016 surveys (which covered all three areas), and the q estimated for the 2012 and 2014 surveys (which covered only two). The penalty was lognormal (mean = 0.88, CV = 1.4%), and estimated from the distribution of biomass between areas observed in 2011, 2013, and 2016. This means that the 2012 and 2014 surveys were assumed to cover 88% of the area (relative biomass) covered in 2011, 2013, and 2016, which high precision (low CV). Similarly, the q for the Old plume survey in 2010 was uniform, with a penalty on the ratio on the q between the 2011, 2013, and 2016 surveys and that on the 2010 survey (which covered just one area): lognormal (mean = 0.3, CV = 0.075). Subsequent Old plume survey q s for 2009–2002 were all uniform, but with penalties on their sequential q ratios, where the mean of the penalty changed linearly such that the q for the 2002 Old plume survey would be 0.7; all penalties were lognormal, with assumed CVs of 0.1 (CVs for these penalties could not be estimated). Compared to the base run, this “ratio- q ” sensitivity run placed greater emphasis on maintaining the relativity between sequential acoustic biomass estimates.

Trawl survey data

Research trawl surveys of the Spawning Box during July were completed from 1984 to 1994, using three different vessels: FV *Otago Buccaneer*, FV *Cordella*, and RV *Tangaroa* (Figure 10). A consistent area was surveyed using fixed station positions (with some random second phase stations each year).

Figure 10: The Spawning Box trawl survey biomass indices (assuming a catchability of 1 for each vessel), with 95% confidence intervals shown as vertical lines. Vessels indicated as B, FV *Otago Buccaneer*; C, FV *Cordella*; T, RV *Tangaroa*.

The biomass indices were fitted as relative indices with a separate time series for each vessel (with uninformed priors on the q s). The second point in the *Tangaroa* time series, although very large (driven by a single high catch), has a large CV and so is unlikely to have had much effect on the assessment results.

Data from two wide-area surveys by *Tangaroa* in 2004 and 2007 were also used. These surveys covered the area which extends from the western edge of the Spawning Box around to the northern edge of the Andes. The area surveyed did not include the Old-plume, the Northeast Hills, or the Andes. The survey used a random design over sixteen strata grouped into five sub-areas. The trawl net used was the full-wing and relatively fine mesh ‘ratcatcher’ net. The surveys covered the same survey area as the Spawning Box trawl surveys from 1984 to 1994 as well as additional strata to the east. In 2007, the survey ran from 4–27 July and 62 trawl tows were completed. In 2004, the survey ran from 7–29 July and 57 trawl tows were completed.

The surveys had almost identical estimates of total biomass in each year (17 000 t) with low CVs (10% and 13% respectively). They were fitted as relative biomass with an uninformed prior on the q .

Length frequencies

The length frequencies from all of the trawl surveys were fitted in the model as multinomial random variables. Effective sample sizes (N) were taken from Dunn (2007) for the Spawning Box surveys and were assumed equal to the number of tows for the wide-area surveys (across all surveys the effective N s ranged from about 20–80). Trawl survey length frequencies were fitted assuming that all mature fish were selected, but immature fish were selected assuming capped-logistic ogives. One selectivity ogive for immature fish was shared by the *Buccaneer*, *Cordella*, and *Tangaroa* Spawning Box surveys, with a second ogive for the immature fish caught in the *Tangaroa* wide-area survey.

Length frequencies from the commercial fisheries were developed by Hicks (2006) and also fitted in the model. For the Spawning Box and associated flat ground fishery, three years of length-frequency data from the period 1989–91 were combined into a single length-frequency that was centred on 1990, and four years 2002–05 were combined and centred on 2004. In a similar way, for Andes four years 1992–95 were combined and centred on 1993, three years 1997–99 combined and centred on 1998, and five years combined 2001–05 and centred on 2003. For the eastern hills, seven years 1991–97 were combined and centred on 1995, and five years 2001–05 combined and centred on 2003. These were fitted as multinomial with effective sample sizes ranging from 8–38.

Age frequencies

Age frequencies were developed for the Old-plume and Rekohu plume in 2012, and for the Old-plume, Rekohu, and the Crack in 2013 and 2016 (Doonan et al 2014a, b; 2017). Approximately 300 otoliths were randomly selected from each area in 2012 and 2016, and 250 from each area in 2013. The fish in the Old-plume were noted to be generally older than those in the Rekohu plume. The fish from the Crack, showed a mixture of ages from new spawners (20–30 years) through to much older fish (80–100 years). In the base model, the age frequencies were combined across areas and fitted as multinomial with effective sample sizes of 50 (2012) and 60 (2013 and 2016) respectively, reflecting the low number of trawls from which samples were taken.

4.2.3 Model runs and results

In the base model, the Old-plume time series was assumed to be unreliable in terms of trend and therefore each point from 2002 to 2010 was given its own q ; also, natural mortality (M) was fixed at 0.045. There were several important sensitivity runs: assume that the Rekohu plume first occurred in 2007; adjust M and the mean of the priors by 20% (the standard *LowM-Highq* and *HighM-Lowq* runs, see Orange Roughy Introduction); and assume penalties on acoustic q -ratios.

In the base model, the main parameters estimated were: virgin (unfished, equilibrium) biomass (B_0), maturity ogive, trawl-survey selectivities, fisheries selectivities, CV of length-at-mean-length-at-age for ages 1 and 100 years (linear relationship assumed for intermediate ages), and year class strengths (YCS) from 1930 to 1990 (with the Haist parameterisation and “nearly uniform” priors on the free parameters). There were also the numerous acoustic and trawl-survey qs .

Model diagnostics

The base model provided good MPD fits to the data. The MPD fits to the acoustic indices were good, except the biomass observed in 2016 was lower than predicted (Figure 11). The normalised residuals of the acoustic indices for the base MCMC model were similarly good, and showed no apparent trend, although the 2016 biomass estimate was substantially lower than predicted (Figure 12).

The posteriors for the acoustic qs were shifted to the left of the priors for the surveys covering all three spawning aggregations (2011, 2013, and 2016), indicating that the predicted biomass was higher than expected (Figure 13). For the Old-plume time series, posteriors were sometimes shifted towards the left of the priors, but more often to the right, indicating the predicted biomass was more often lower than expected (Figure 13).

The MPD fits to the trawl indices were good but the model-predicted biomass had a shallower decline than that estimated from the indices from the *Buccaneer* and *Cordella* surveys (Figure 11). Also, the model did not fit the very large increase in the *Tangaroa* Spawning Box survey (Figure 11).

The fits to the age frequencies were as good as can be expected given the inconsistent shape of the age frequencies in the consecutive years, for example relatively more fish aged 30–40 years in 2013 (Figure 14).

The MPD fits to the commercial length frequencies were excellent except the 1990 Spawning Box and eastern flats commercial fishery length frequency (Figure 15). Likewise the fits to the trawl survey length frequencies were excellent (Figure 15). The capped-logistic selectivities assumed for immature fish estimated that a small proportion of immature fish were caught, and therefore were able to fit the long tails observed on the left-hand side of the Spawning Box survey length frequencies.

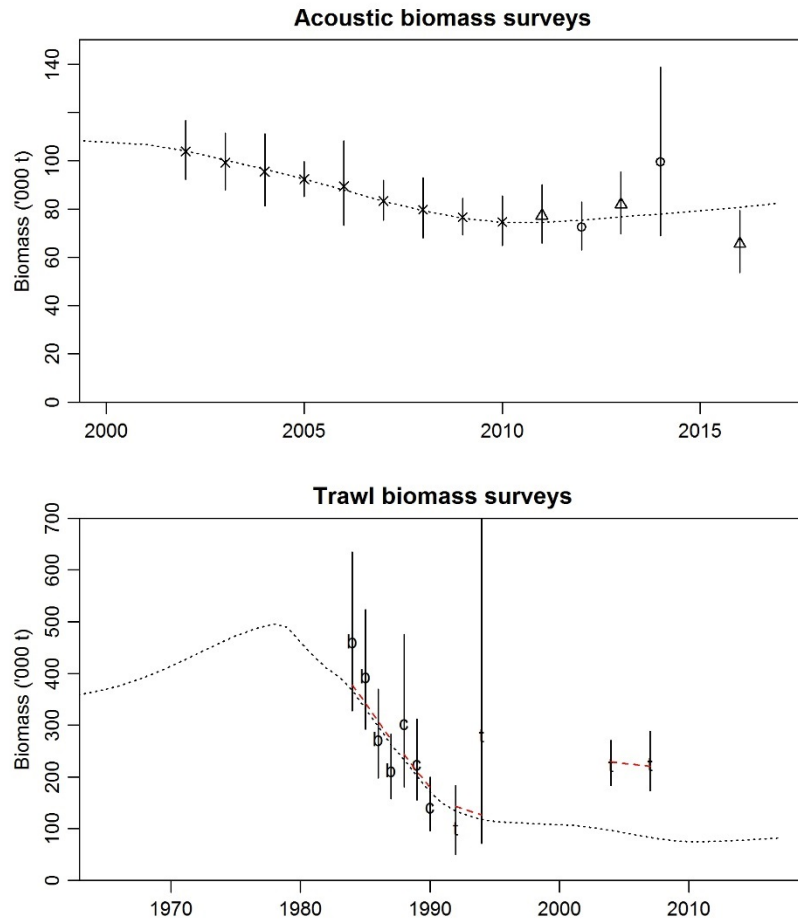

Figure 11: ESCR, MPD, base: fit to the acoustic indices: (top) spawning biomass trajectory and scaled acoustic indices; x, Old plume surveys; Δ, three-area 2011, 2013 and 2016 surveys; ○, two-area 2012 and 2014 surveys; (bottom) the spawning biomass trajectory (dotted line) and fits of the trawl surveys to their respective vulnerable biomass (red dashed lines), for b, *Buccaneer*; c, *Cordella*; t (1992 and 1994), *Tangaroa* Spawning Box; t (2004 and 2007), *Tangaroa* wide-area. Vertical lines indicate 95% confidence intervals.

Figure 12: ESCR, MCMC base: normalized residual for the acoustic indices. The box covers 50% of the distribution for each index and the whiskers extend to 95% of the distribution.

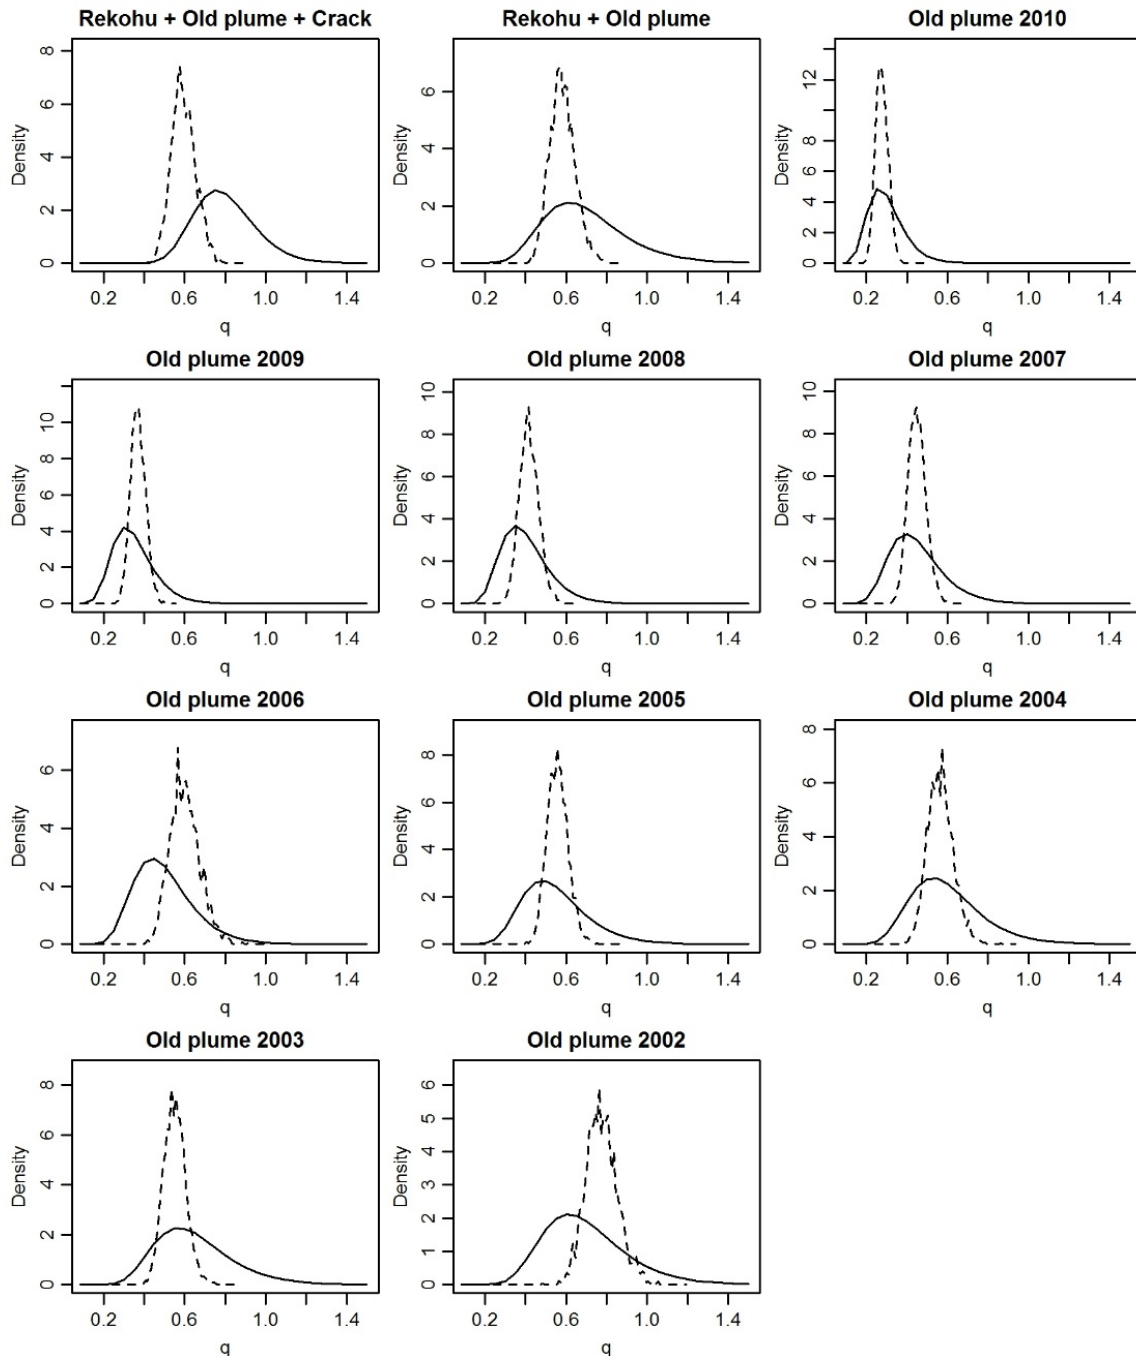

Figure 13: ESCR, MCMC base: prior (solid lines) and posterior distributions (broken lines) for acoustic q s.

Numerous sensitivity runs were conducted at the MPD stage (see also Cordue 2014a). The sensitivity runs included in management advice from the 2014 assessment were maintained in the 2017 assessment (Table 11). These runs included evaluating the effect of estimating M , assuming the Rekohu plume was not formed until 2007, the two “bounding” runs, where M and the mean of the acoustic q priors were shifted by 20% (High M -low q ; low- M high q). Additional sensitivity runs included the ratio- q run, and runs assuming lognormal priors for YCS.

In the ratio- q sensitivity run, the fits to most acoustic indices were good, but the 2003 and 2016 biomass estimates were lower than predicted (Figure 16). The MCMC normalised residuals for the acoustic indices had a similar pattern, with the 2016 biomass estimate substantially lower than predicted. The median estimates of stock size and status were very similar to those from the base run (<1% difference); however, the 95% credible intervals from the ratio- q run were about 30% broader.

With a lognormal YCS prior, the estimated stock size and status was sensitive to the assumed σ_R (variability in YCS). Estimates from the nearly-uniform YCS prior (assumed in the base model) were roughly equivalent to a lognormal YCS prior with $\sigma_R = 0.6$.

The residuals of the base model indicated that additional process error of around 20% was needed to adequately fit the 2011–16 acoustic biomass index, notably the low estimate for 2016; however, adding the process error made no material difference to the outcome ($\%B_0$ was still 33%). The Deepwater Fisheries Assessment Working Group concluded that additional process error should only be added when there was a clear rationale for this to take place, and after further observations had been added to the series.

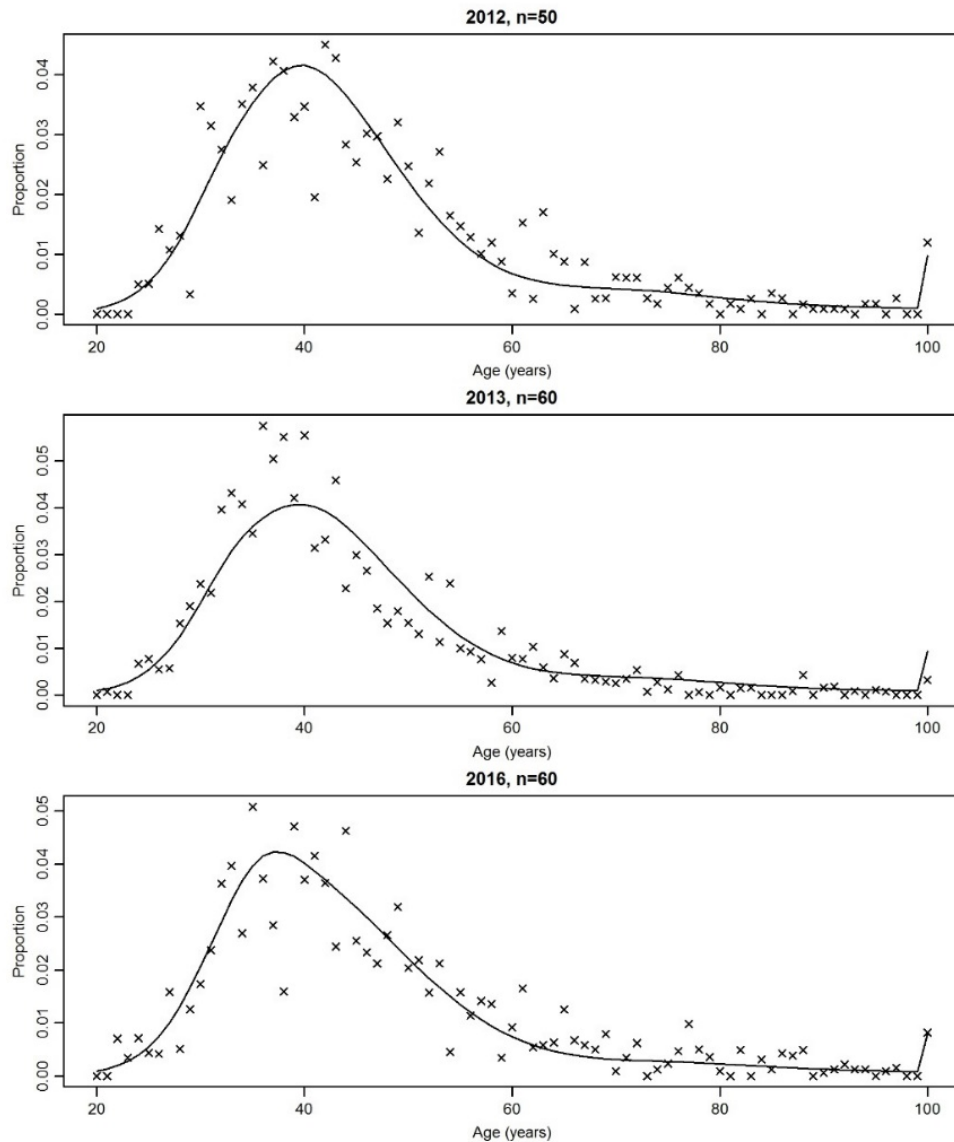

Figure 14: ESCR, MPD base: fits (lines) to the spawning season age frequencies (points); n is the effective sample size.

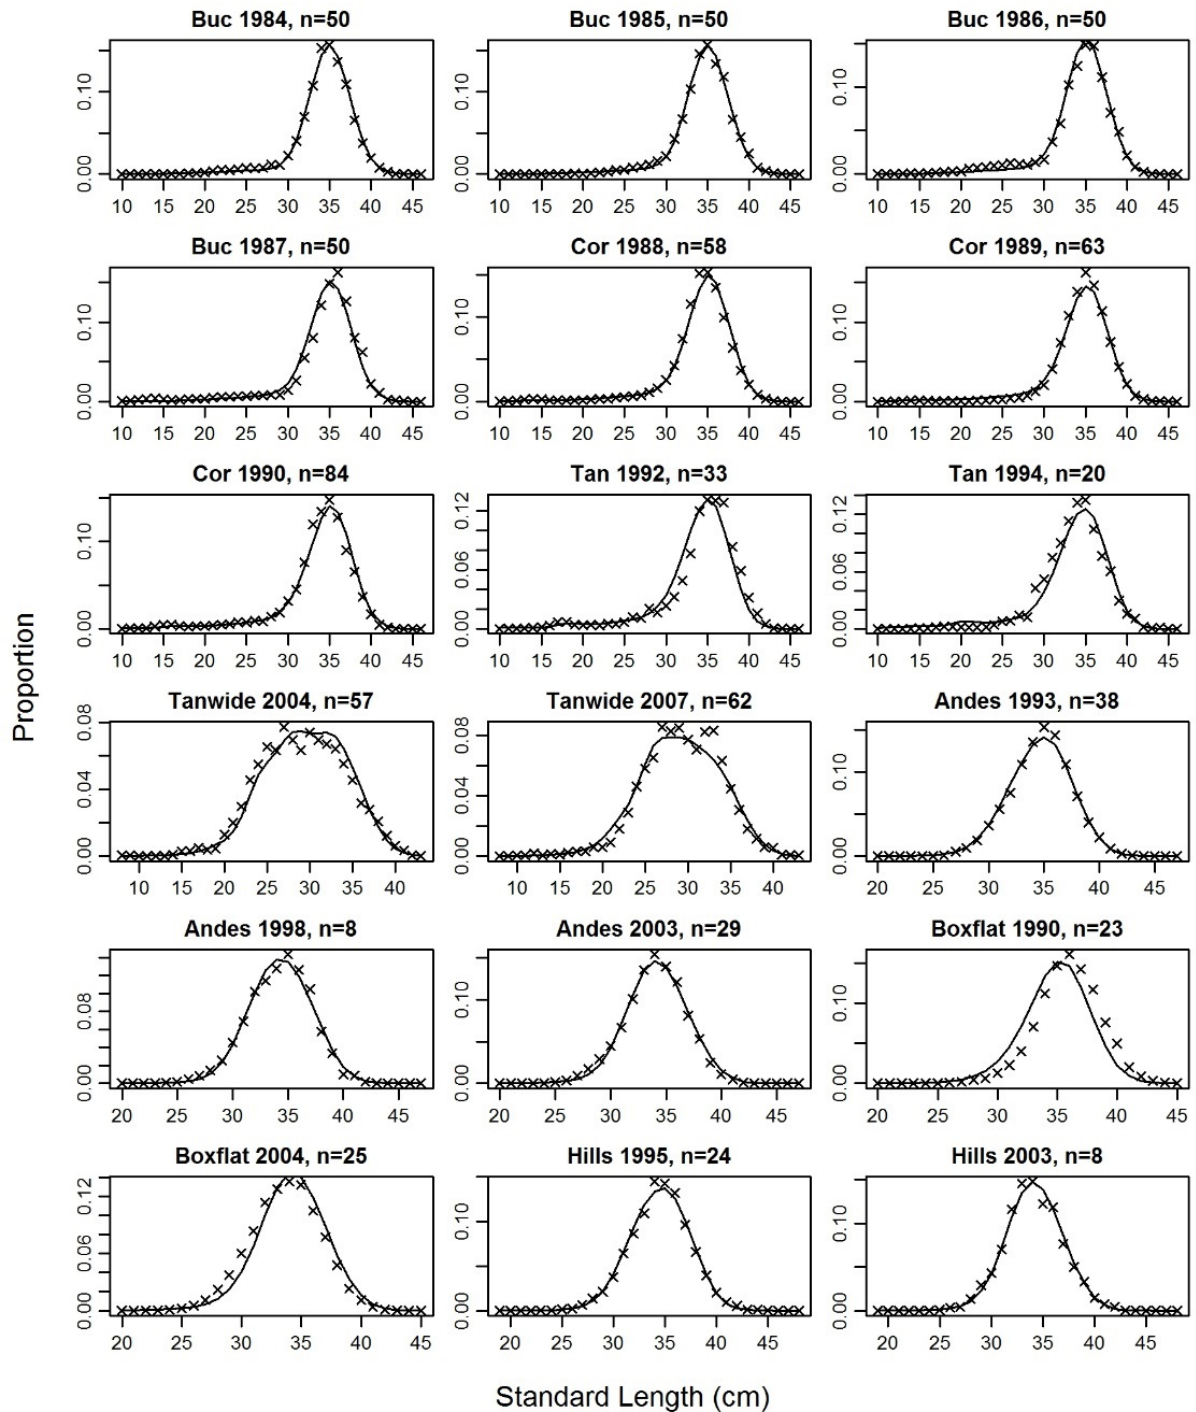

Figure 15: ESCR, MPD base: fits (lines) to the length frequencies (x) for the *Buccaneer* surveys (Buc), *Cordella* surveys (Cor), *Tangaroa* Spawning Box surveys (Tan), *Tangaroa* wide-area surveys (Tanwide), commercial Andes fishery (Andes), commercial Spawning Box and eastern flats fishery (Boxflat), and eastern hills fishery (Hills); n is the effective sample size.

Figure 16: ESCR, MPD, ratio- q : fit to the acoustic indices: (left) spawning biomass trajectory and scaled acoustic indices; x, Old plume surveys; Δ, three-area 2011, 2013 and 2016 surveys; o, two-area 2012 and 2014 surveys; (right) MCMC normalized residual for the acoustic indices (note 2016 is below -3 sd). The box covers 50% of the distribution for each index and the whiskers extend to 95% of the distribution.

MCMC results

For the base model, MCMC convergence diagnostics were good once the three chains (with random starting values near the MPD estimate) had been run for 15 million iterations. Some technical changes were made to improve chain convergence, including re-estimation of the covariance matrix; these improved diagnostics whilst giving results very similar to the model without the changes.

Virgin biomass, B_0 , was estimated to be about 313 000 t for the base model with median estimates ranging from 300 600–363 100 t for the four sensitivity runs presented (Table 11). Current stock status was similar across the base and the first two sensitivity runs (Table 11). The lower stock status when M was estimated reflects the lower estimates of M (0.034 rather than 0.045). For the two “bounding” runs, where M and the mean of the acoustic q priors were shifted by 20%, current stock status was estimated below the biomass target range of 30–50% B_0 for the pessimistic *LowM-Highq* run and within the target range for the optimistic *HighM-Lowq* run (Table 11).

Table 11: ESCR, MCMC estimates of virgin biomass (B_0) and stock status (B_{2017} as % B_0) for the base model and four sensitivity runs.

	M	B_0 (000 t)	95% CI	B_{2017} (% B_0)	95% CI
Base	0.045	313.3	281.2–346.9	33	28–37
Estimate M	0.034	363.1	304.3–416.1	27	21–34
Rekohu 2007	0.045	300.6	270.8–332.4	31	26–35
Low M -High q	0.036	335.5	308.3–362.8	25	20–29
High M -Low q	0.054	306.3	272.8–342.7	42	36–47

The estimated YCS show little variation across cohorts but do exhibit a long-term trend (Figure 17). The stock status trajectory shows a steady decline from the start of fishery until the mid-1990s, where it remained in the 20–30% range until an upturn in about 2010 (Figure 18).

For the base model, there was an 86% probability that the stock was above 30% B_0 in 2017. Therefore, for the base model, the stock is considered to be fully rebuilt according to the Harvest Strategy Standard (at least a 70% probability that the lower end of the management target range of 30–50% B_0 has been achieved).

Figure 17: ESCR base, MCMC estimated “true” YCS (R_y/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

Figure 18: ESCR base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. Dotted lines indicate the hard limit (10% B_0) and soft limit (20% B_0), dashed lines the biomass target range (30–50% B_0).

Fishing intensity was estimated in each year for each MCMC sample to produce a posterior distribution for fishing intensity by year. Fishing intensity is represented in terms of the median exploitation rate and the Equilibrium Stock Depletion (ESD). For the latter, a fishing intensity of $U_{x\%B_0}$ means that fishing (forever) at that intensity will cause the SSB to reach deterministic equilibrium at $x\% B_0$ (e.g., fishing at $U_{30\%B_0}$ forces the SSB to a deterministic equilibrium of 30% B_0). Fishing intensity in these units is plotted as 100–ESD so that fishing intensity ranges from 0 ($U_{100\%B_0}$) up to 100 ($U_{0\%B_0}$).

Estimated fishing intensity was within or above the target range ($U_{30\%B_0}$ – $U_{50\%B_0}$) for most years of the fishery except 1994–95 to 2000–01 and after 2009–10, after 2009–10 fishing intensity was below the target range (Figure 19).

ORANGE ROUGHY (ORH 3B)

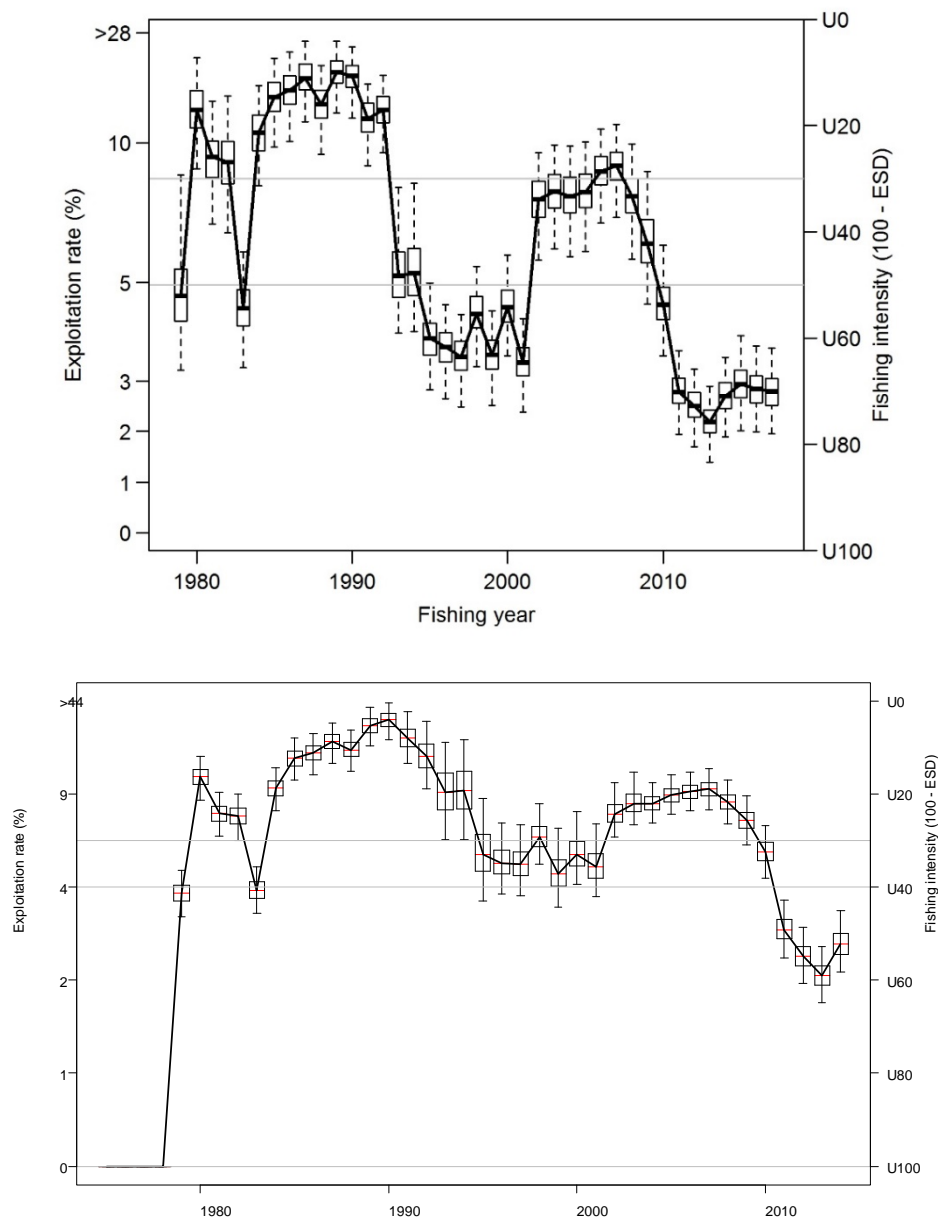

Figure 19: ESCR base, MCMC estimated fishing-intensity trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The fishing-intensity range associated with the biomass target of 30–50% B_0 is marked by horizontal lines.

Projections

Five-year biomass projections were made for the Base model run assuming future catches to be the TACC (3 100 t). For each projection scenario, future recruitment variability was sampled from actual estimates between 1940 and 1979.

At the TACC, the SSB is predicted to slowly increase over the next five years, and the probability of the SSB going below the soft or hard limits is zero (Table 12).

Table 12: ORH 3B ESCR Bayesian median and 95% credible intervals (in parentheses) of projected B_{2022} , B_{2022} as a percentage of B_0 , and B_{2022}/B_{2017} (%) for the model runs.

Model run	Catch	B_{2022}	B_{2022} (% B_0)	B_{2022}/B_{2017} (%)	$p(B_{2022} < 0.2 B_0)$	$p(B_{2022} < 0.1 B_0)$
Base	3 100 120 300 (100 200–147 600)	39 (34–45)	119 (114–127)	0	0	

Biological reference points, management targets and yield

Orange roughy stocks with model based stock assessments are managed according to the Harvest Control Rule (HCR) that was developed in 2014 using a Management Strategy Evaluation (MSE) (Cordue 2014b). The HCR has a target management range of 30–50% B_0 .

Yield estimates are not reported for this stock.

4.3 Puysegur

A Bayesian stock assessment was conducted for the Puysegur stock in 2017 using very similar methods to those used in the 2014 orange roughy stock assessments of ESCR, NWCR, MEC, and ORH7A (Cordue 2014a). An age-structured population model was fitted to an acoustic-survey estimate of spawning biomass, two trawl-survey indices and associated length frequencies, two spawning-season age frequencies, and a small number of length frequencies from the commercial fishery.

4.3.1 Model structure

The model was single-sex and age-structured (1–120 years with a plus group), with maturity estimated separately (i.e., fish were classified by age and as mature or immature). Two time steps were used to model a non-spawning season fishery and a spawning season fishery. Spawning was taken to occur after 50% of the spawning-season mortality and 100% of mature fish were assumed to spawn each year.

The catch history as reported in Table 5 (see above) was split into a spawning (June–August) and a non-spawning season (October–May and September) using the ratio of estimated catches, with the addition of catches during 2005, 2006, and 2015 when fish were caught during acoustic surveys. The catch for 2016–17 was assumed to be zero. Natural mortality was fixed at 0.045 and the stock-recruitment relationship was assumed to follow a Beverton-Holt function with steepness of 0.75. The remaining fixed biological parameters are given in table 2 of the Orange Roughy Introduction section (ESCR growth parameters were assumed).

4.3.2 Input data and statistical assumptions

There were four main data sources used in the assessment: an acoustic-survey spawning biomass estimate in 2015 from the main spawning hill (Goomzy); two age frequencies during the spawning seasons in 1992 and 2015; biomass indices and length frequencies from trawl surveys in 1992 and 1994; and scaled length frequencies developed from Scientific Observer data collected from the commercial fishery in 1994 and 1997.

Acoustic estimate

Two types of acoustic-survey estimates were available for use in the assessment: an estimate from a 38 kHz hull-mounted system during an AOS survey (AOS is a multi-frequency towed system, e.g., see Kloser et al 2011) and 38 kHz estimates from a hull-mounted system. The reliability of the data from the different surveys and the two main hills was considered and only the estimate from the 2015 survey on Goomzy was used in the base model (Table 13). The estimates from Godiva were unreliable because the surveyed marks contained a mix of species (Hampton et al 2005, 2006). In 2005 and 2006 it was not clear that the marks on Goomzy were exclusively orange roughy but in 2015 there was strong evidence from both trawling and the multi-frequency system that the surveyed marks were almost exclusively orange roughy (Ryan & Tilney 2016).

Table 13: Acoustic survey estimates of spawning biomass available to the stock assessment. Only the 2015 estimate from Goomzy was used in the base model.

Year	Area	Snapshots	Estimate (t)	CV (%)
2005	Godiva	3	2 600	23
	Goomzy	4	4 000	22
2006	Godiva	4	900	51
	Goomzy	3	3 200	50
2015	Godiva	2	180	Not calculated
	Goomzy	2	4 200	

The acoustic estimate in 2015 from Goomzy was assumed to represent “most” of the spawning biomass in that year. This was modelled by treating the acoustic estimate as relative biomass and estimating the proportionality constant (q) with an informed prior. The prior was lognormally distributed with a mean of 0.8 (i.e., “most” = 80%) and a CV of 19% (see Orange Roughy Introduction section).

Age frequencies

Age frequencies were developed for the *Giljanus* spawning-season trawl survey in 1992 (Clark & Tracey 1993) and the targeted trawling on spawning marks during the 2015 acoustic survey (Ryan & Tilney 2016)(Ian Doonan, NIWA, pers. comm.). Approximately 400 otoliths were used for each age frequency and CVs were calculated for each proportion at age from bootstrapping. In 2015, the mode (for the smoothed distribution) is at about 40 years whereas in 1992 the mode is closer to 60 years (Figure 20). It is notable that in both years the ages extend out to at least 130 years (Figure 20). In the base model, the age frequencies were fitted as multinomial with effective sample sizes of 80 and 60 respectively. The sample size of 80 is the approximate number of trawl stations during the survey in 1992 and the value of 60 was derived from the between year ratio of equivalent multinomial sample sizes derived from the bootstrap CVs.

Figure 20: Puysegur: age frequencies from 1992 and 2015 used in the base model. The red lines were produced using the lowest smoother in R.

Trawl survey data

Trawl surveys of the Puysegur area were undertaken on *Tangaroa* in 1992 and 1994 (Clark & Tracey 1994, Clark et al 1996). However, the timing of the surveys was not ideal with the second survey being more than a month later than the first (Puysegur strata occupied in 1992: 8 August–11 September, and in 1994: 24 September–23 October). An analysis of seasonal CPUE suggested that catch rates in the later period could be expected to be 50% of those in the earlier period. Also, an analysis of fish length data suggested that larger fish were caught in the June–August period – the period taken to be the “spawning season” in the model (although spawning occurs in July). It appears that during the June–August period larger fish are more available to the fishing fleet and could have been more available to the trawl survey. There was a very large reduction in the biomass indices for such a short period (Table 14).

Table 14: Trawl survey biomass indices for all fish from the *Tangaroa* trawl surveys of the Puysegur area in 1992 and 1994. The CVs given are those used in the modelling and include no process error.

	Biomass index (t)	CV (%)
1992	6630	28
1994	1160	24

To allow for a possible reduction in availability between the 1992 and 1994 surveys, due to the change in timing, the selectivity for the trawl survey was modelled separately for mature and immature fish and an availability parameter for mature fish was estimated for the 1994 survey. The length frequencies from the trawl surveys are bimodal which could be partly explained by two groups of fish distinguished by maturity (Figure 21).

Figure 21: Puysegur: length frequencies for the *Tangaroa* trawl surveys in 1992 and 1994 (fitted in the model as beginning of year in 1993 and 1995). The effective samples sizes of $N = 70$ were the approximate number of stations in each survey.

Length frequencies (commercial fishery)

Scientific observer coverage of the Puysegur fishery was very patchy over the small number of years when the fishery operated. The best coverage was in the 1993–94 fishing year when there were 15 samples in the non-spawning season and 44 samples in the spawning season. The next best year, when more than one month was sampled in the non-spawning season, was 1996–97 when there were 6 non-spawning season samples and 3 spawning season samples. Scaled length frequencies were produced in those two years for the spawning and non-spawning seasons. The data were assumed to be multinomial with effective sample sizes equal to the number of samples.

4.3.3 Model runs and results

In the base model, the acoustic estimate from Goomzy in 2015 was used, with the *Tangaroa* trawl survey data, and natural mortality (M) was fixed at 0.045. There were six main sensitivity runs: exclude the *Tangaroa* trawl survey data; low weight on the age frequencies; high weight on the age frequencies; estimate M ; and the *LowM-Highq* and *HighM-Lowq* “standard” runs (see Orange Roughy Introduction section). There were additional sensitivities: treating the trawl surveys as strictly comparable; using lognormal priors on the free year class strength parameters; alternative fixed non-spawning season

fishing selectivities; adding a 5% overrun to the catch history; and using a higher CV on the acoustic q prior.

In the base model, the main parameters estimated were: virgin (unfished, equilibrium) spawning biomass (B_0), maturity ogive, trawl-survey selectivity, CV of length-at-mean-length-at-age for ages 1 and 120 years (linear relationship assumed for intermediate ages), and year class strengths (YCS) from 1917 to 1990 (with the Haist parameterisation and “nearly uniform” priors on the free parameters).

Model diagnostics

The model provided good MPD fits to the data. Residuals were examined mainly at the MCMC level and these were all acceptable suggesting that the data weightings (CVs and effective sample sizes) were reasonable.

The marginal posterior distribution of the acoustic q shifted somewhat to the left of the prior but remains well within the distribution of the prior (Figure 22).

The MPD sensitivity runs where the trawl surveys were assumed strictly comparable, despite the difference in timing, were unable to fit the decline in the trawl indices and showed poorer fits to the trawl survey length frequencies than the base model. The objective function decreased by 7 likelihood units when the availability parameter for 1994 was estimated (which supports the inclusion of the single additional parameter).

When lognormal priors were used for the free YCS parameters the trawl survey indices were fitted adequately (as the availability parameter was estimated) but the fits to the composition data (length and age frequencies) were degraded compared to the base model (which used nearly uniform priors on the free YCS parameters). The worst example of the poor fits was for the *Tangaroa* trawl survey length frequency in 1994. The reason for the poorer fits to the composition data was because the use of a lognormal prior severely constrained the estimated YCS. The near uniform prior allows much more freedom in the pattern of estimated YCS. Behaviour in the MCMC runs is much improved for the lognormal priors but there is the issue that the choice of sigmaR is arbitrary (see the Orange Roughy Introduction section).

Figure 22: Puysegur: the marginal posterior distribution of the acoustic q (histogram) compared to its prior (red line). The black dot marks the median of the marginal posterior.

MCMC Results

For the base model, and the sensitivity runs, MCMC convergence diagnostics for virgin biomass (B_0) and stock status were very good. B_0 was estimated to be between 12 000–26 000 t for all runs (Table 15). Current stock status was similar across the base and the first four sensitivity runs (Table 15). The slightly lower stock status when M was estimated reflects the lower estimates of M (0.040 rather than 0.045). For the two “bounding” runs, where M and the mean of the acoustic q prior were shifted by 20%, median current stock status was within or above the biomass target range of 30–50% B_0 for both runs (Table 15). The sensitivity with a higher CV on the acoustic q prior gave similar results to the base model with a slighter higher B_0 and stock status. The 5% overrun model gave almost identical results to the base model. All other sensitivity runs gave stock status estimates within the range covered by the *LowM-Highq* and *HighM-Lowq* models.

Table 15: Puysegur: MCMC estimates of virgin biomass (B_0) and stock status (B_{2017} as % B_0) for the base model and six sensitivity runs.

	M	B_0 (000 t)	95% CI	B_{2017} (% B_0)	95% CI
Base	0.045	17	13–23	49	36–62
No trawl	0.045	17	13–24	51	39–64
Low AF	0.045	15	12–21	46	34–61
High AF	0.045	18	14–26	51	39–63
Estimate M	0.040	18	13–25	47	34–61
LowM-Highq	0.036	18	14–23	42	30–55
HighM-Lowq	0.054	17	12–25	57	44–69

For the base model, (and all sensitivities) the stock is considered to be fully rebuilt according to the Harvest Strategy Standard (at least a 70% probability that the lower end of the management target range of 30–50% B_0 has been achieved).

The estimated YCS show a trend across cohorts with above average recruitment prior to 1950 with below average recruitment up until about 1980 (Figure 23). The variation in the more recent (true) YCS is due to variation in depletion levels across the MCMC samples (and hence different levels of recruitment were generated from the stock-recruitment relationship).

Figure 23: Puysegur base, MCMC estimated “true” YCS (R_t/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

The estimated spawning-stock biomass (SSB) trajectory showed a declining trend from 1990 (when the fishery started) through to 1998 when the fishery was closed (Figure 24). Since 1998 the estimated biomass has increased steadily and has been well within the target range for the last decade (Figure 24).

ORANGE ROUGHY (ORH 3B)

Figure 24: Puysegur base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The hard limit (red), soft limit (blue), and biomass target range (green) are marked by horizontal lines.

Fishing intensity was estimated in each year for each MCMC sample to produce a posterior distribution for fishing intensity by year. Fishing intensity is represented in terms of the median exploitation rate and the Equilibrium Stock Depletion (ESD). For the latter, a fishing intensity of $U_{x\%B_0}$ means that fishing (forever) at that intensity will cause the SSB to reach deterministic equilibrium at $x\% B_0$ (e.g., fishing at $U_{30\%B_0}$ forces the SSB to a deterministic equilibrium of 30% B_0). Fishing intensity in these units is plotted as 100–ESD so that fishing intensity ranges from 0 ($U_{100\%B_0}$) up to 100 ($U_{0\%B_0}$).

Estimated fishing intensity was above $U_{20\%B_0}$ for most of the history of the fishery before it was closed in 1998; it was briefly in the target range ($U_{30\%B_0}$ – $U_{50\%B_0}$) in 2006 when there was a combined acoustic and trawl survey (Figure 25).

Figure 25: Puysegur base, MCMC estimated fishing-intensity trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The fishing-intensity range associated with the biomass target of 30–50% B_0 is marked by horizontal lines.

Biological reference points, management targets and yield

Orange roughy stocks with model based stock assessments are managed according to the Harvest Control Rule (HCR) that was developed in 2014 using a Management Strategy Evaluation (MSE) (Cordue 2014b). The HCR has a target biomass range of 30–50% B_0 .

Yield estimates are not reported for this stock.

4.4 Research needs

- Ongoing monitoring of the stock will be required if the fishery is reopened (Update: the Puysegur orange roughy fishery was reopened in 2017).
- This is best done with acoustic survey estimates conducted during the spawning season.
- Additional representative age frequencies from the commercial catch and from spawning aggregations will also be required.
- It would also be useful to estimate von Bertalanffy growth parameters specifically for Puysegur orange roughy, rather than using the estimates from the Chatham Rise.

5. STATUS OF THE STOCKS

5.1 Chatham Rise

Stock Structure Assumptions

Chatham Rise orange roughy are believed to comprise two biological stocks; these are assessed and managed separately: one on the Northwest of the Chatham Rise and the other ranging throughout the East and South Rise. This assumed stock structure is based on the presence of two main areas where spawning takes place simultaneously, and observed and inferred migration patterns of adults and juveniles. These two biological stocks form the bulk of the ORH 3B Fishstock. They are geographically separated from all other ORH 3B biological stocks.

- **Northwest Chatham Rise**

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Base model only
Reference Points	Management Target: Biomass range 30–50% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Fishing intensity range $U_{30\%B_0}$ – $U_{50\%B_0}$
Status in relation to Target	B_{2017} was estimated at 38% B_0 . Very Likely (> 90%) to be at or above the lower end of the management target range
Status in relation to Limits	B_{2017} is Exceptionally Unlikely (< 1%) to be below the Soft Limit. B_{2017} is Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Overfishing is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Historical trajectory of spawning biomass (%B₀), median exploitation rate (%) and fishing intensity (100-ESD) (base model, medians of the marginal posteriors). The biomass target range of 30–50 % B₀ and the corresponding exploitation rate range are marked in green. The soft limit (20% B₀) is marked in blue and the hard limit (10% B₀) in red. Note that the Y-axis is non-linear.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass reached its lowest point in 2004 and has increased consistently since then. According to the Harvest Strategy Standard, the stock is considered to be fully rebuilt (at least a 70% probability that the lower end of the management target range of 30–50% B ₀ has been achieved).
Recent Trend in Fishing Intensity or Proxy	Fishing intensity decreased sharply from 2010 to 2011 and has remained below the overfishing threshold since then.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	At both the TACC (1 250 t) and current agreed catch (1 043 t), the biomass is expected to stay steady or increase over the next 5 years.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	At both TACC and current agreed catch limit: Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Exceptionally Unlikely (< 1%) at both TACC and current agreed catch limit.

Assessment Methodology and Evaluation

Assessment Type	Level 1 - Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2018	Next assessment: 2021

Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Acoustic estimates of spawning biomass on Graveyard (1999, 2012–13) and Morgue (1999, 2012, 2016). - Trawl survey age frequency and proportion-spawning-at-age (1994). - 17 years of length frequency data. - Morgue age frequency (2016); only as a sensitivity 	<p>1 – High Quality</p> <p>1 – High Quality 1 – High Quality 2 – Medium or Mixed Quality: potential non-representative sampling</p>
Data not used (rank)	<ul style="list-style-type: none"> - CPUE - Trawl surveys of hills (1990–2002) - Wide-area acoustic survey estimates - Chatham Rise trawl survey deepwater stations (2010–2016) - Egg survey estimate 	<p>3 – Low Quality: unlikely to be indexing stock-wide abundance</p> <p>3 – Low Quality: unlikely to be indexing stock-wide abundance</p> <p>2 – Medium or Mixed Quality: large potential bias due to mixed-species</p> <p>2 – Medium or Mixed Quality: variable indices</p> <p>3 – Low Quality: survey design assumptions not met</p>
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - The largest source of uncertainty is the proportion of the NWCR spawning stock that is indexed by the acoustic survey in each year. - In the base case, patterns in year class strengths are based on only one year of age composition data. - The time series of abundance indices is short and restricted to the period of lower stock status. 	

Qualifying Comments

Estimates of stock biomass are sensitive to the means of the q priors.

Fishery Interactions

Main bycatch species are smooth oreo, black oreo, rattails, deepwater dogfish and hoki, with lesser bycatches of Johnson's cod and ribaldo. Low productivity bycatch species include deepwater sharks, skates and corals. Observed incidental captures of protected species include corals, low numbers of seabirds and occasional New Zealand fur seals.

- **East and South Chatham Rise**

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Base model only
Reference Points	<p>Management Target: Biomass range 30–50% B_0</p> <p>Soft Limit: 20% B_0</p> <p>Hard Limit: 10% B_0</p> <p>Overfishing threshold: Fishing intensity range $U_{30\%B_0}–U_{50\%B_0}$</p>
Status in relation to Target	B_{2017} was estimated to be 33% B_0

ORANGE ROUGHY (ORH 3B)

	Likely (> 60%) to be at or above the lower end of the management target range
Status in relation to Limits	B_{2017} is Very Unlikely (< 10%) to be below the Soft Limit B_{2017} is Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Overfishing is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Historical trajectory of spawning biomass ($\%B_0$), median exploitation rate (%) and fishing intensity (100-ESD) (base model, medians of the marginal posteriors). The biomass target range of 30–50 $\%B_0$ and the corresponding exploitation rate range are marked in green. The soft limit (20% B_0) is marked in blue and the hard limit (10% B_0) in red. Note that the Y-axis is non-linear.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	The spawning biomass is estimated to have been slowly increasing over the last six years.
Recent Trend in Fishing Intensity or Proxy	Fishing intensity (exploitation rate) is estimated to have been below the lower end of the target range in the last seven years.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	Biomass is expected to increase slowly at catches equal to the TACC.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	At the catch limit (3 100 t): Soft Limit: Exceptionally Unlikely (< 1%) Hard Limit: Exceptionally Unlikely (< 1%)

Assessment Methodology and Evaluation

Assessment Type	Level 1 – Full Quantitative Stock Assessment
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions

Assessment Dates	Latest assessment: 2017	Next assessment: 2021
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Four short time series of biomass indices from research trawl surveys - Acoustic indices from research surveys of spawning plumes (Old-plume, Rekohu plume, Crack) - Age frequencies from the spawning plumes in 2012, 2013, and 2016 - Length frequencies from commercial fisheries 	<ul style="list-style-type: none"> 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	<ul style="list-style-type: none"> - CPUE - Acoustic surveys of hills (hull-mounted transducers) - Wide-area acoustic survey estimates - Chatham Rise deepwater trawl survey stations (2010–2016) 	<ul style="list-style-type: none"> 3 – Low Quality: unlikely to be indexing stock-wide abundance 3 – Low Quality: major species identification and dead zone issues 2 – Medium or Mixed Quality: large potential bias due to mixed-species 2 – Medium or Mixed Quality: variable indices
Changes to Model Structure and Assumptions	None.	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - The largest source of uncertainty is the proportion of the ESCR spawning stock that is indexed by the acoustic survey in each year. - Stock status is dependent on the timing of the appearance of the Rekohu spawning plume, which is unknown. - Patterns in year class strengths are based on only 3 years of age composition data. 	

Qualifying Comments

Estimates of stock biomass are sensitive to the means of the q priors.

Fishery Interactions

Main bycatch species are smooth oreo, black oreo, deepwater dogfish, hoki and rattails, with lesser bycatches of slickhead, Johnson's cod and morids. Low productivity bycatch species include deepwater sharks and dogfish and also corals. Observed incidental captures of protected species include corals, low numbers of seabirds and occasional New Zealand fur seals.

• 5.2 Southern ORH 3B fisheries

There are several other small fisheries in ORH 3B in the southern waters of which Puysegur appears to be the largest stock.

Puysegur

Stock Status	
Year of Most Recent Assessment	2017
Assessment Runs Presented	Base model only
Reference Points	Management Target: Biomass range 30–50% B_0

ORANGE ROUGHY (ORH 3B)

	Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Fishing intensity range $U_{30\%B_0}$
Status in relation to Target	B_{2017} was estimated at 49% B_0 . Very Likely (> 90%) to be at or above the lower end of the management target range
Status in relation to Limits	B_{2017} is Exceptionally Unlikely (< 1%) to be below the Soft or Hard Limits
Status in relation to Overfishing	An agreed closure of the fishery was in place until 2017. Overfishing in 2017 is Exceptionally Unlikely (< 1%) to be occurring

Historical Stock Status Trajectory and Current Status

Historical trajectory of spawning biomass (% B_0), median exploitation rate (%) and fishing intensity (100-ESD) (base model, medians of the marginal posteriors). The biomass target range of 30–50% B_0 and the corresponding exploitation rate range are marked in green. The soft limit (20% B_0) and the hard limit (10% B_0) are marked in red. Note that the left-hand Y-axis is non-linear.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass reached its lowest point in 1998 and has increased steadily since then. According to the Harvest Strategy Standard, the stock is now considered to be fully rebuilt (at least a 70% probability that the lower end of the management target range of 30–50% B_0 has been achieved).
Recent Trend in Fishing Intensity or Proxy	Fishing intensity has been close to zero since the fishery was closed in 1997–98 with the exception of 2005, 2006, and 2015 when surveys were conducted.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	No projections were conducted
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Current catch is zero

Probability of Current Catch or TACC causing Overfishing to continue or to commence	Current catch is zero
---	-----------------------

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2017	Next assessment: 2020
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Acoustic estimate of spawning biomass on Goomzy (2015) - Trawl survey indices and length frequencies (1992, 1994) - Age frequencies (1992, 2015) - 2 years of length frequency data	1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	- CPUE - Winter trawl surveys (1991, 1992, 2006) - Acoustic survey estimates (2005, 2006) - Additional commercial length frequencies	3 – Low Quality: unlikely to be indexing stock-wide abundance 2 – Medium or Mixed Quality: unlikely to be indexing stock-wide abundance 2 – Medium or Mixed Quality: large potential bias due to mixed species 2 – Medium or Mixed Quality: not enough months sampled within each year
Changes to Model Structure and Assumptions	- The previous assessment was in 1998. - Model now based on spawning biomass rather than transition-zone mature biomass. - Age data included to enable estimation of year class strengths rather than assuming deterministic recruitment. - Trawl survey indices better modelled to allow for difference in timing - A more stringent data quality threshold was imposed on data inputs (e.g., CPUE indices not used)	
Major Sources of Uncertainty	-The largest source of uncertainty is the proportion of the Puysegur spawning stock that is indexed by the acoustic survey in 2015. - The single acoustic estimate is the only recent biomass index. - Patterns in year class strengths are based on only two years of age frequencies.	
Qualifying Comments		
-		
Fishery Interactions		
Historically the Puysegur orange roughy fishery included black and smooth oreos, deepwater dogfish, black cardinal fish, slickheads and rattails as significant bycatch. Interactions with other species are currently being characterised.		

- **Auckland Islands (Pukaki South)**

The Deepwater Working Group examined the data on orange roughy catch and effort from the Auckland Islands area in 2006, and found that there had been relatively little fishing activity in this area in the previous few years. There were insufficient data to conduct a standardised CPUE analysis, and it was believed that unstandardised CPUE did not provide a suitable index of relative abundance. Therefore, a stock assessment could not be carried out.

- **Other fisheries**

In 2006 the Deepwater Working Group examined the data on orange roughy catch and effort from other parts of ORH 3B – the Bounty Islands, Pukaki Rise, Snares Island and the Arrow Plateau – and agreed that there were insufficient data to carry out standardised CPUE analyses for any of these areas.

ORANGE ROUGHY CHALLENGER PLATEAU (ORH 7A)

1. FISHERY SUMMARY

1.1 Commercial fisheries

Historically, the fishery mainly occurred in the south-western region of the Challenger Plateau, both inside and outside the EEZ. Fish were caught throughout the year, with most effort in winter when the orange roughy form aggregations for spawning. Domestic vessels caught most of the quota. Total catches peaked at 10 000–12 000 t annually from 1986–87 to 1988–89 (Table 1). Total catch and ORH 7A catch were less than 2 100 t annually from 1990–91 until the closure in 2000–01 (Table 1, Figure 1), when the TACC for this stock was reduced to 1 t.

Recent surveys have shown an increase in biomass in the area. On 1 October 2010 the TACC was increased from 1 t to 500 t, with a 25 t allowance for other mortality, raising the TAC to a total of 525 t. This was allow research surveys to be conducted using commercial fishing vessels. The TACC was further increased following a stock assessment in 2014.

Table 1: Reported catches (t) and TACs (t) from 1980–81 to present. QMS data from 1986-present.

†FSU data

*This is a minimum value, because of unreported catches by foreign vessels fishing outside the EEZ.

+Unknown distribution of catch between inside and outside the EEZ

Catches taken during winter trawl and acoustic surveys were approximately 200 t each year.

1.2 Recreational fisheries

There is no known recreational fishing for orange roughy in this area.

1.3 Customary non-commercial fisheries

There is no known customary non-commercial fishing for orange roughy in this area.

1.4 Illegal catch

There is no quantitative information available on illegal catch.

ORANGE ROUGHY (ORH 7A)

Figure 1: Reported commercial landings and TACC for ORH 7A.

1.5 Other sources of mortality

In previous stock assessments, catch overruns from various sources (including lost and/or discarded fish, use of nominal tray weights and low conversion factors) have been estimated as: 1980–81 to 1987–88, 30%; 1988–89, 25%; 1989–90, 20%; 1990–91, 15%; 1991–92 to 1992–93, 10%; 1993–94 onwards, 5%.

2. BIOLOGY

Biological parameters used in this assessment are presented in the Biology section at the beginning of the Orange Roughy Introduction section.

3. STOCKS AND AREAS

There is no new information on orange roughy stock structure beyond that presented in previous assessment documents.

Orange roughy on the southwest Challenger Plateau (Area 7A, including Westpac Bank) are regarded as a single separate stock. Size structure, parasite composition, flesh mercury levels, allozyme frequency and mitochondrial DNA studies show differences to other major fisheries. Spawning occurs at a similar time to fish on the Chatham Rise, Puysegur Bank, Ritchie Banks, Cook Canyon and Lord Howe Rise.

4. STOCK ASSESSMENT

A model-based Bayesian stock assessment was carried out for this stock in 2014. It was the first model-based assessment since 2005 (MFish 2006) when a Bayesian model was used to update the 2000 assessment (Annala et al 2000, Field & Francis 2001). From 2010 to 2013, assessments were conducted using an ad hoc approach which combined the virgin biomass estimate from the 2000 assessment and current biomass estimates from annual combined acoustic and trawl surveys (see Clark et al 2006, NIWA & FRS 2009, Doonan et al 2010, Hampton et al 2013, Hampton et al 2014, Cordue 2010, 2012, 2013).

The 2014 assessment for this stock was one of four orange roughy assessments carried out in 2014 which all used similar methods (see Orange Roughy Introduction). An age-structured population model was fitted to combined acoustic and trawl-survey estimates of spawning biomass, two trawl-survey time series of spawning biomass, and three trawl-survey age frequencies.

4.1 Model structure

The model was single-sex and age-structured (1–100 years with a plus group), with maturity estimated separately (i.e., fish were classified by age and as mature or immature). Two time steps were used: a full year of natural mortality followed by an instantaneous spawning season and fishery on the spawning fish. The fishery selectivity was uniform across ages (for spawning fish) and 100% of mature fish were assumed to spawn each year.

The catch history was constructed from the total catches in Table 1 and the over-run percentages in Section 1.5. Natural mortality was assumed to be fixed at 0.045 and the stock-recruitment relationship was assumed to follow a Beverton-Holt function with steepness of 0.75. The remaining fixed biological parameters are given in the Orange Roughy Introduction.

4.2 Input data and statistical assumptions

There were three main data sources for observations fitted in the assessment: spawning biomass estimates from combined acoustic and trawl surveys (2006, 2009–2013); an early trawl survey time series of relative spawning biomass (1987–1989); and three age frequencies from the trawl surveys (1987, 2006, and 2009).

4.2.1 Research surveys

Trawl surveys of orange roughy on the Challenger Plateau were conducted regularly from 1983 to 1990. However, a variety of vessels and survey strata were used which makes comparisons problematic (Dunn et al 2010). Wingtip biomass estimates in 1983–1986 ranged from 100 000–185 000 t but the 1989 and 1990 survey estimates were much lower at approximately 10 000 t. From these early trawl surveys a “comparable area” time series, defined by Clark & Tracey (1994) and covering the period 1987–89, was selected for use in the assessment to provide some information on the early rate of spawning biomass decline (Table 2).

In 2005, a new series of combined trawl and acoustic surveys was begun using the FV *Thomas Harrison* with a survey area comparable to that used from 1987–1990 (Clark et al 2005). The survey was repeated in 2006 (with an enlarged survey area) and was then conducted annually from 2009–2013 (Clark et al 2006, NIWA & FRS 2009, Doonan et al 2010, Hampton et al 2013, Hampton et al 2014). It was apparent from the later surveys that the 2005 survey did not cover an appropriate area as the spawning biomass distribution had shifted somewhat in the intervening years. The surveys from 2006 onwards appear to have covered the bulk of the spawning biomass. The data from these surveys have been analysed to produce three types of indices used in this assessment: combined acoustic and trawl survey spawning biomass; acoustic estimates of spawning plumes; trawl survey indices of spawning biomass.

Combined acoustic and trawl survey indices

The method of Cordue (2010, 2012) was used to produce combined acoustic and trawl survey indices for 2010 and 2013 (Table 2). This method used an estimate of orange roughy trawl vulnerability to allow the trawl survey estimates to be combined with the acoustic estimates (trawl estimates are essentially scaled down by a vulnerability distribution with a mean of 1.66). The method accounts for observation error and potential bias in orange roughy target strength by combining priors and “error distributions” centred on the observations (Cordue 2010, 2012). Strata 9–11 were excluded from the estimates as they covered hills and/or very rough terrain (i.e., were not included because orange roughy are probably not equally vulnerable to the trawl gear on the hills and on the flat).

The 2010 and 2013 surveys were used in this way for different reasons. In 2010, the survey specifically excluded spawning plumes from the trawl survey strata and the plumes were surveyed acoustically. In other years, plumes were not explicitly excluded from the trawl survey area and a number of random trawl stations did obtain very high catch rates in the vicinity of plumes. The 2010 design was specifically aimed at combining the acoustic and trawl survey estimates.

The 2013 survey had three trawl stations with very high catch rates in two strata which were near where spawning plumes were surveyed. As a consequence, the trawl survey index had a very high CV of 51%. It seemed preferable to replace the trawl estimates from the two “plume” strata with the corresponding acoustic estimates and combine them with the remaining trawl estimates (following Cordue 2012) which gave a combined index with a lower CV of 35% (Table 2).

ORANGE ROUGHY (ORH 7A)

The estimates were used as relative biomass with a lognormal informed prior on the q . The total survey area was assumed to cover 90% of the spawning biomass and the three excluded strata (9–11) were estimated to account for 15% of the surveyed biomass (from years in which they were surveyed). The mean of the informed prior was therefore $0.9 \times 0.85 = 0.77$. The CV was chosen so that the CVs for the prior and the observation were equal in 2010 and the combined CV from observation error and the prior were equal to 0.3 (2010) and 0.35 (2013) (the CVs of the distribution-estimates of spawning biomass). This gave a prior CV of 0.21.

Acoustic estimate for two plumes in 2009

Two spawning plumes were acoustically surveyed on 4–5 July 2009. The main plume was covered by two snapshots and had a much higher average biomass than was seen in a comparable survey conducted during the previous few days (28 June–2 July): 16 800 t compared to 6700 t. A second plume was also surveyed with a single snapshot (6300 t) and the combined estimate was 23 100 t (Table 2). This unusual event led to the conclusion that “most” of the 2009 spawning biomass was present in the two surveyed plumes.

This was modelled by treating the acoustic estimate as relative biomass and estimating the proportionality constant (q) with an informed prior. The acoustic q prior described in the Orange Roughy Introduction was used: a mean of 0.8 (i.e., “most” = 80%) and a CV of 19%.

Trawl survey indices

The spawning biomass estimates from the *Thomas Harrison* trawl surveys in 2006, 2009–2012 (Table 2) were used as relative biomass with an informed prior. They excluded the rough terrain strata 9–11 and the mean of the informed prior was: $0.9 \times 0.85 \times 1.66 = 1.27$ (allowing for total-survey availability (0.9), exclusion of strata 9–11 (0.85) and trawl vulnerability – mean of estimated vulnerability distribution = 1.66). Given the problematic nature of these trawl surveys (fish pluming and moving within the area), a process error CV of 20% was added to the estimated CVs (Table 2).

Table 2: Biomass indices used in the stock assessment. The model CV is the observation error used in the base model. A 20% process error CV has been added to the sample CV for the trawl indices. The CV for the combined acoustics and trawl estimates has been split between the informed q -prior (CV = 21%) and the observation error in the model.

Series	Year	Biomass index (t)	CV (%)	Model CV (%)
<i>Amaltal Explorer</i>	1987	75 040	26	33
	1988	28 954	27	34
	1989	11 062	11	23
<i>Thomas Harrison</i>	2006	13 987	27	34
	2009	34 864	24	31
	2011	18 425	26	33
	2012	22 451	18	27
	2013	18 993	51	55
Acoustics & trawl	2010	14 766	30	21
	2013	13 637	35	28
Two plumes	2009	23 095	25	25

Age frequencies

Age frequencies were available from three of the trawl surveys for use in the assessment. A previous analysis produced age frequencies for the 1987 *Amaltal Explorer* survey and the 2009 *Thomas Harrison* survey (Doonan et al 2013), although that study was based on a relatively small number of otoliths, it showed that the 2009 age frequency had much younger fish than the 1987 age frequency. For the stock assessment, the existing age frequencies were augmented with an increased number of otoliths (for a total of about 300 for each survey) and a new age frequency (from about 300 otoliths) was produced for the 2006 *Thomas Harrison* survey.

The age frequencies were assumed to be multinomial and were assigned effective sample sizes of $300/5 = 60$ (with the sample size reflecting the number of trawl stations rather than the number of otoliths).

4.3 Model runs and results

In the base model, natural mortality (M) was fixed at 0.045. There were numerous MPD sensitivity runs but three main sensitivities are presented in this report: estimate M ; and the LowM-High q and HighM-Low q runs (see the Orange Roughy Introduction section for specifications).

In the base model the main parameters estimated were: virgin biomass (B_0), the maturity ogive, and year class strengths (YCS) from 1925 to 1985 (with the Haist parameterisation and “nearly uniform” priors on the free parameters). There were also the proportionality constants (q) for the two trawl survey time series, the combined acoustic and trawl estimates (2010, 2013) and the two-plumes estimate in 2009.

4.3.1 Model diagnostics

The model provided good MPD fits to the biomass indices although the 2009 trawl index had a large positive residual (Figure 2, top right). The large positive residual in 2009 was balanced by negative residuals in the other years. In a sensitivity run, taken through to MCMC, the 2009 index was removed. This had no effect on the stock status estimates for the MPD or MCMC runs but it did provide an improved fit to the other biomass indices (the 2009 index is not influential in terms of important derived estimates but does affect the residual pattern). The MCMC normalised residuals for the biomass indices show a similar pattern to the MPD fit, but the only large residuals are for the *Amaltal Explorer* time series (Figure 3). The magnitude of the *Amaltal Explorer* residuals could be reduced by adding more process error, but this would not affect any of the important assessment estimates (the same results are obtained if the *Amaltal* time series is removed altogether).

The MPD fit to the age frequencies was very good (Figure 4).

The biomass indices with the informed priors are free to “move” somewhat as they are relative. The MPD estimated q s were not very different from the mean of the informed priors (Figure 5, blue dots). The same is not true for the MCMC runs, as the *Thomas Harrison* q and the combined acoustics and trawl q have both moved to the left appreciably (Figure 5, right-hand plots). Although they have moved, the posteriors are still well within the distribution of the priors, leaving the estimated q s credible.

Numerous MPD sensitivity runs were performed. These showed that the main drivers of the estimated stock status were natural mortality (M) and the means of the informed q priors (lower M and higher mean q give lower stock status; higher M and lower mean q give higher stock status). The base model was robust to changes in the relative weights of the different data sets. Large changes in estimated 2014 stock status only occurred when deterministic recruitment was assumed (49% B_0 compared to 32% B_0 for the base) or when recent biomass indices were halved or doubled (respectively 18% B_0 and 50% B_0).

ORANGE ROUGHY (ORH 7A)

Figure 2: MPD fit to biomass indices: top left: *Amaltal Explorer*; top right: *Thomas Harrison*; bottom left: combined acoustics and trawl; bottom right: indices scaled to spawning biomass (using MPD estimated q_s). Vertical lines are 95% CIs (model CVs).

Figure 3: MCMC base: normalised residuals for the biomass indices. The box covers 50% of the distribution for each index and the whiskers extend to 95% of the distribution. “A&T” denotes combined acoustics and trawl (2010, 2013); “Amaltal” the *Amaltal Explorer* series; “Thomas” the *Thomas Harrison* series; and “Plumes” the two-plumes estimate from 2009.

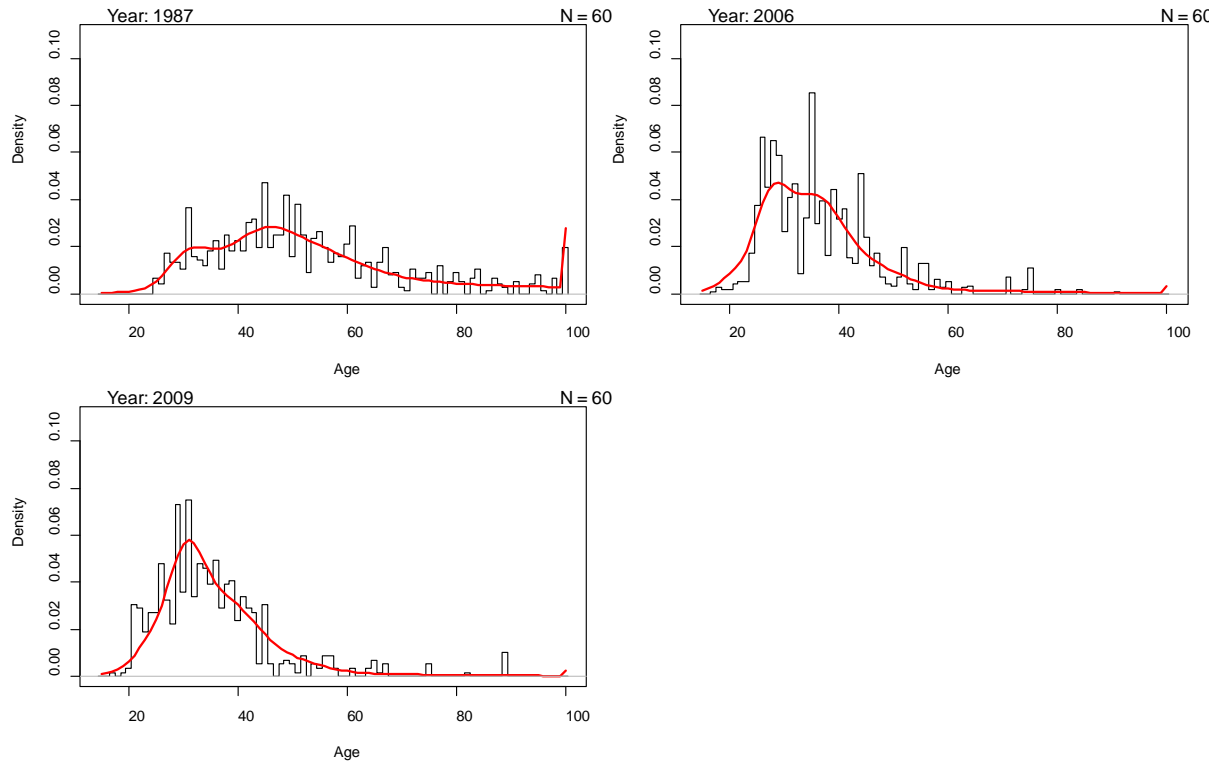

Figure 4: MPD fit to spawning-season trawl-survey age frequencies for the 1987, 2006 and 2009 surveys ($N = 60$ is the assumed effective sample size). Observations are square-topped black lines; model predictions are the smooth red lines.

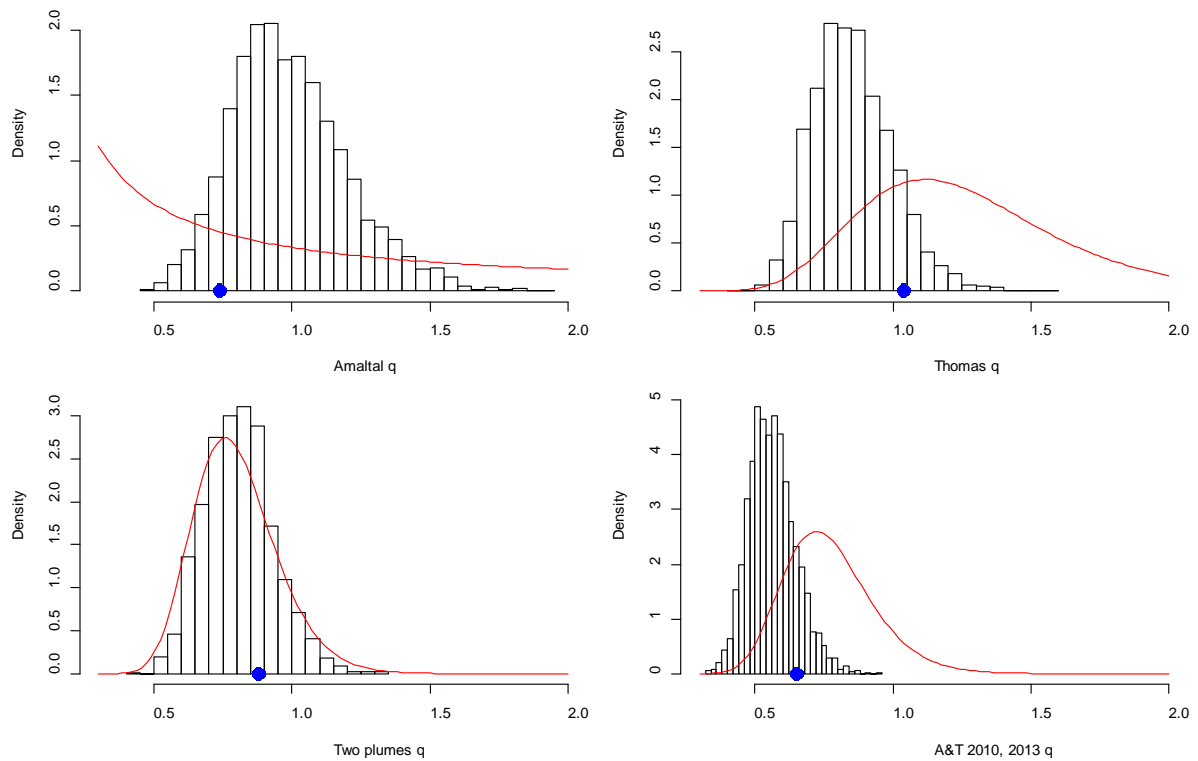

Figure 5: Base model MCMC diagnostics: prior and posterior distributions for the biomass time series qs (prior in red, posterior black histograms; the blue dot is the MPD estimate. “Amaltal q ” denotes the *Amaltal Explorer* series; “Thomas q ” the *Thomas Harrison* series; “Two plumes q ” the two-plumes estimate from 2009; and “A&T 2010, 2013 q ” denotes combined acoustics and trawl for those years).

MCMC results

For the base model, and the sensitivity runs, MCMC convergence diagnostics were excellent. Virgin biomass (B_0) was estimated to be about 90 000 t for all runs (Table 3). Current stock status was similar for the base and the estimate- M run (Table 3). The slightly lower stock status when M was estimated reflects the lower estimate of M (0.039 rather than 0.045). For the two runs, where M and the mean of the informed q priors were shifted either up or down by 20%, median current stock status was estimated within the biomass target range of 30–40% B_0 for the *LowM-Highq* run but well above the range for the *HighM-Lowq* run (Table 3).

Table 3: MCMC estimates of virgin biomass (B_0) and stock status (B_{2014} as % B_0) for the base model and three sensitivity runs.

	M	B_0 (000 t)	95% CI	B_{2014} (% B_0)	95% CI
Base	0.045	88	82–96	42	35–49
Estimate M	0.039	92	84–100	38	30–47
LowM-Highq	0.036	90	85–97	33	27–40
HighM-Lowq	0.054	88	81–97	51	44–59

The estimated YCS show little variation across cohorts but exhibit a long-term trend (Figure 6). The most recent 10 years (1976–1985) of estimates (those resampled for short-term projections) are about average.

Figure 6: Base, MCMC estimated “true” YCS (R_y/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

The stock status trajectory showed a steep decline to about 10% B_0 in 1990, reflecting the large removals during the initial fish-down phase of this fishery (Figure 7). From 1990 stock status remained at about 10% B_0 until a strong upturn in 2000 (Figure 7). Rebuilding has taken only 14 years to reach the top of the 30–40% biomass target range because the fishery was closed in 2001 and reopened in 2011, with relatively limited catches since then (see Table 1).

For the base model, the stock is now considered to be fully rebuilt according to the Harvest Strategy Standard (at least a 70% probability that the lower end of the management target range of 30–40% B_0 has been achieved).

Figure 7: Base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The hard limit 10% B_0 (red), soft limit 20% B_0 (blue), and biomass target range 30–40% B_0 (green) are marked by horizontal lines.

Fishing intensity was estimated in each year for each MCMC sample to produce a posterior distribution for fishing intensity by year. Fishing intensity is represented in term of the median exploitation rate and the Equilibrium Stock Depletion (ESD). For the latter, a fishing intensity of $U_{x\%B_0}$ means that fishing (forever) at that intensity will cause the SSB to reach deterministic equilibrium at $x\%$ B_0 (e.g., fishing at $U_{30\%B_0}$ drives the SSB to a deterministic equilibrium of 30% B_0). Fishing intensity in these units is plotted as 100–ESD so that fishing intensity ranges from 0 ($U_{100\%B_0}$) up to 100 ($U_{0\%B_0}$).

Estimated fishing intensity was within or above the target range ($U_{30\%B_0}$ – $U_{40\%B_0}$) up until the closure of the fishery in 2001. Since then, it has been well below the target range (Figure 8).

Figure 8: Base, MCMC estimated fishing-intensity trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The fishing-intensity range associated with the biomass target of 30–40% B_0 is marked by horizontal lines.

ORANGE ROUGHY (ORH 7A)

Biological reference points, management targets and yield

MCMC estimates of deterministic B_{MSY} and associated values were produced for the base model. The yield at 35% B_0 (the mid-point of the target range) was also estimated. There is little variation in the reference points and associated values across the MCMC samples (Table 4).

There are several reasons why deterministic B_{MSY} is not a suitable target for use in fisheries management. First, it assumes a harvest strategy that is unrealistic in that it involves perfect knowledge (current biomass must be known exactly in order to calculate the target catch) and annual changes in TACC (which are unlikely to happen in New Zealand and not desirable for most stakeholders). Second, it assumes perfect knowledge of the stock-recruit relationship, which is often poorly known. Third, it would be very difficult with such a low biomass target to avoid the biomass occasionally falling below 20% B_0 , the default soft limit according to the Harvest Strategy Standard.

Table 4: Base, MCMC estimates of deterministic equilibrium SSB and long-term yield (% B_0 and tonnes) for U_{MSY} and $U_{35\%B_0}$. The equilibrium SSB at U_{MSY} is deterministic B_{MSY} and the yield is deterministic MSY.

Fishing intensity		SSB (% B_0)	Yield (% B_0)	Yield (t)
U_{MSY}	Median	24.5	2.1	1853
	95% CI	22.9–24.9	2.1–2.1	1728–2009
$U_{35\%B_0}$	Median	35.0	2.0	1764
	95% CI	35.0–35.0	2.0–2.0	1645–1912

The estimate of long-term yield associated with $U_{35\%B_0}$ for the 2014–15 fishing year is 2128 t (95% CI 1673–2694 t).

Projections

Five-year projections were conducted (with resampling from the last 10 estimated YCS, 1976–1985) for two different constant catch assumptions: 500 t (the current TACC); and 2100 t (the current estimated yield at $U_{35\%B_0}$). In each case a 5% catch over-run was assumed. Projections were done for the base model and for the *LowM-Highq* sensitivity model (as a “worst case” scenario).

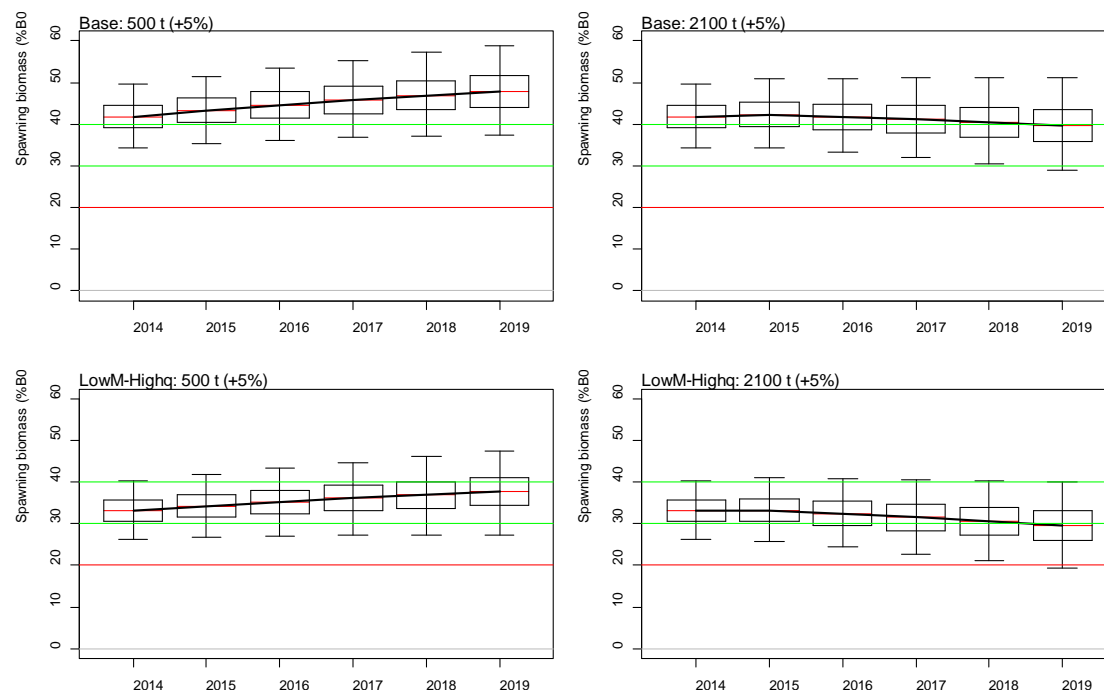

Figure 9: Base, MCMC projections. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The projections are for the model and annual catch indicated (a 5% catch over-run was included in each year). The target biomass range (30–40% B_0) is indicated by horizontal green lines, the hard limit (10% B_0) by a red line and the soft limit (20% B_0) by a blue line.

At the current TACC (500 t), SSB is predicted to increase steadily over the next five years for both models (Figure 9). At the catch associated with $U_{35\%B_0}$ (2100 t), SSB is predicted to decrease slightly

for both models (Figure 9). For both models and both constant catch scenarios the estimated probability of SSB going below either the soft limit (20% B_0) or hard limit (10% B_0) is zero. For the *LowM-Highq* model there is a small probability (1.5% and 3% respectively) of the SSB falling below 20% B_0 in 2018 or 2019 under a 2 100 t catch (Figure 9).

5. STATUS OF THE STOCK

Orange roughy on the southwest Challenger Plateau (Area 7A, including Westpac Bank) are regarded as a single separate stock.

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	Base model only
Reference Points	Management Target: Biomass range 30–40% B_0 ¹ Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Fishing intensity range $U_{30\%B_0}$ – $U_{40\%B_0}$
Status in relation to Target	B_{2014} was estimated to be 42% B_0 Very Likely (> 90%) to be at or above the lower end of the management target range and About as Likely as Not (40–60%) to be at or above the upper end of the management target range
Status in relation to Limits	B_{2014} is Very Unlikely (< 10%) to be below the Soft Limit B_{2014} is Exceptionally Unlikely (< 1%) to be below the Hard Limit
Status in relation to Overfishing	Fishing intensity in 2014 was estimated at $U_{71\%B_0}$ Overfishing is Very Unlikely (< 10%) to be occurring

¹ The information presented reflects the management settings that were in place in 2014 which guided the projections and advice provided. The management settings were updated in August 2014 and the management target range and a harvest control rule are now being implemented for key orange roughy fisheries (ORH 3B Northwest Rise, ORH 3B East & South Rise, ORH 7A). The change does not change the status of the stocks in relation to reference points but it has led to a reduction in yield estimates. For more information on current management settings, please see Cordue, 2014. (<http://deepwater.co.nz/wp-content/uploads/2014/08/Cordue-2014-A-Management-Strategy-Evaluation-for-Orange-Roughy.-ISL-Re....pdf>)

ORANGE ROUGHY (ORH 7A)

Historical Stock Status Trajectory and Current Status

Historical trajectory of spawning biomass (%B₀), median exploitation rate (%) and fishing intensity (100-ESD) (base model, medians of the marginal posteriors). The biomass target range of 30–40% B₀ and the corresponding exploitation rate (fishing intensity) range are marked in green. The soft limit (20% B₀) is marked in blue and the hard limit (10% B₀) in red. Note that the Y-axis is non-linear.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	The spawning biomass is estimated to have been steadily increasing since just before the fishery closure in 2000–2001. According to the Harvest Strategy Standard, the stock is now considered to be fully rebuilt (at least a 70% probability that the lower end of the management target range of 30–40% B ₀ has been achieved).
Recent Trend in Fishing Intensity or Proxy	The fishery was closed in 2000–01 and re-opened in 2010–11, with fisheries surveys conducted since 2005. Fishing intensity has been low and fairly constant since 2010–11.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	Biomass is expected to increase at the current TACC (500 t) or decrease slightly over the next 5 years at annual catches of up to 2100 t.
Probability of Current Catch or TACC causing Biomass to remain below, or to decline below, Limits	Soft Limit: Very Unlikely (< 10%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full quantitative stock assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment: 2014	Next assessment: 2019
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	-Combined acoustic and trawl survey estimates of spawning biomass (2010, 2013) -Acoustic survey estimate of spawning biomass from two plumes in 2009 -Two trawl survey time series: 1987–1989 and 2006, 2009–2012 -Age frequencies from the trawl surveys in 1987, 2006, and 2009	1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	-CPUE -Acoustic surveys of hills (hull-mounted transducers) -Early trawl surveys with different vessels covering different areas	3 – Low Quality: unlikely to be indexing stock-wide abundance 2 – Medium or Mixed Quality: species identification and dead zone problems 2 – Medium or Mixed Quality: not a consistent time series
Changes to Model Structure and Assumptions	-The previous model-based assessment was in 2005. Recent assessments have been based on an ad hoc method. -The current assessment is fully quantitative and based on spawning biomass rather than transition-zone mature biomass. -Age data were included to enable estimation of year class strengths rather than assuming deterministic recruitment. - A more stringent data quality threshold was imposed on data inputs (e.g. CPUE indices were not used).	
Major Sources of Uncertainty	-The proportion of the stock that is indexed by the combined acoustic and trawl survey. -Patterns in year class strengths are based on only 3 years of age composition data.	

Qualifying Comments

- Estimates of stock biomass are sensitive to the means of the q priors. In addition, when higher CVs were used for the informed acoustic q priors, the median estimates of biomass and stock status were slightly higher and the confidence intervals were wider with a much higher upper bound.

Fishery Interactions

Historically, the main bycatch species were deepwater dogfish, spiky oreos and ribaldo. Since the fishery re-opened with a low level of catch and effort and fishing during the spawning season, bycatch levels have been relatively low at about 4%. The bycatch of low productivity species includes deepwater sharks, deepsea skates and corals. With limited fishing effort, there have been no observed incidental captures of protected species other than corals since 2002–03.

ORANGE ROUGHY WEST COAST SOUTH ISLAND (ORH 7B)**1. FISHERY SUMMARY****1.1 Commercial fisheries**

From 1 October 2007 the TACC for this stock was reduced to 1 t. Previously the fishery was centred on an area near the Cook Canyon in statistical areas 033, 034 and 705. Up until 1996–97 approximately 80% of the catch was taken in winter (June–July) when fish form aggregations for spawning. From 1997–98 onwards about 50% of the catch was taken in winter. Reported domestic landings and TACCs are shown in Table 1, while the historical landings and TACC for ORH 7B are depicted in Figure 1.

Table 1: Reported landings (t) of orange roughy and TACCs (t) for ORH 7B from 1983–84 to present. QMS data from 1986–present.

Fishing year	Reported landings	TACC
1983–84*	2	-
1984–85*	282	-
1985–86*	1 763	1 558
1986–87*	1 446	1 558
1987–88	1 413	1 558
1988–89	1 750	1 708
1989–90	1 711	1 708
1990–91	1 683	1 708
1991–92	1 604	1 708
1992–93	1 139	1 708
1993–94	701	1 708
1994–95	290	1 708
1995–96	446	430
1996–97	425	430
1997–98	330	430
1998–99	405	430

2009–10	0.04	1
2010–11	0.14	1
2011–12	0.06	1
2012–13	0.25	1
2013–14	0.62	1
2014–15	1.67	1
2015–16	0.27	1
2016–17	0.58	1

*FSU data.

Catches in the early-mid 1990s (especially 1994–95) were well below the TACC. The TACC was reduced to 430 t for the 1995–96 fishing year, then was reduced further to 110 t from 1 October 2001, followed by a further reduction to 1 t in the 2007–08 fishing year.

1.2 Recreational fisheries

There is no known recreational fishery for orange roughy in this area.

1.3 Customary non-commercial fisheries

There is no known customary non-commercial fishing for orange roughy in this area.

1.4 Illegal catch

There is no quantitative information available on illegal catch.

1.5 Other sources of mortality

There is no quantitative information available on other sources of mortality in this fishery.

Figure 1: Reported commercial landings and TACC for ORH 7B (Auckland East).

2. STOCKS AND AREAS

There is no new information which would alter the stock boundaries given in previous assessment documents.

Orange roughy in this fishery are thought to be a single stock. Genetic studies have shown that samples of Cook Canyon orange roughy are significantly different from Challenger Plateau and Puysegur Bank samples. Moreover, the size structure and parasite composition differ from fish on the Challenger Plateau. Spawning occurs at a similar time to fish on the Challenger Plateau and the Puysegur Bank.

3. STOCK ASSESSMENT

The previous assessment for this stock was carried out in 2004 and is summarised in the 2006 Plenary Report. Biomass was estimated to be 17% B_0 (95% confidence interval 14–23%) when CPUE was assumed to be directly proportional to abundance.

An updated assessment was attempted in 2007 with the addition of catch data up to 2005–06 and new standardised CPUE indices. The Working Group rejected the assessment on the basis of the poor fit to the CPUE data. The effect was similar to the result from the 2004 assessment; namely a slow rebuild in recent years, which was not supported by the CPUE data.

3.1 Estimates of fishery parameters and abundance

Commercial catch and effort data are available from 1985 and were examined using both an unstandardised and a standardised analysis. Unstandardised catch rates have declined substantially over the course of the fishery but have shown no clear trend in more recent years (Table 2).

The standardised CPUE analysis has been divided into two series to address reporting form changes: (i) using TCEPR data from 1985–86 through to 1996–97, and (ii) using CELR data from 1990–91 through to 2005–06. In addition, in order to increase vessel linkage across years, it was decided to use all months of data not just that from the winter fishery (June–July) as has been done for previous standardisations.

Table 2: Summary of groomed data from TCEPR and CELR forms.

Fishing year	Number of vessel days	Number of tows	Total estimated catch (t)	Mean daily catch rate (t/tow)	Mean daily catch rate (t/h)
1985–86	138	357	1 544	4.5	2.9
1986–87	132	405	1 250	4.0	2.7
1987–88	132	420	1 250	3.4	2.3
1988–89	133	368	827	2.5	1.6
1989–90	123	356	1 282	4.5	5.6
1990–91	208	632	1 657	2.8	3.3
1991–92	238	810	1 601	2.0	1.4
1992–93	258	784	1 128	1.5	2.3
1993–94	298	708	660	1.1	0.9
1994–95	162	361	320	0.9	1.6
1995–96	66	150	275	2.2	1.7
1996–97	90	182	244	1.3	7.5
1997–98	96	228	170	0.7	0.3
1998–99	188	566	359	0.6	0.2
1999–00	213	647	259	0.4	0.1
2000–01	149	442	162	0.4	0.1
2001–02	117	282	76	0.3	0.1
2002–03	97	292	112	0.4	0.2
2003–04	90	252	118	0.4	0.2
2004–05	121	393	102	0.3	0.1
2005–06	87	257	73	0.3	0.2

The standardised analysis for the TCEPR data used catch per tow in a linear regression model. Indices from this model (Table 3, Figure 2) show a steep decline after the first two years, followed by a more gradual decline and a slight increase in catch rates in 1995–96 and 1996–97.

Table 3: Standardised CPUE indices (relative year effect) based on TCEPR data with number of vessel tows from 1985–86 to 1996–97.

Year	CPUE index	CV	Number of tows	Year	CPUE index	CV	Number of tows
1985–86	1.99	0.20	153	1991–92	0.48	0.23	231
1986–87	2.13	0.23	150	1992–93	0.29	0.23	230
1987–88	1.11	0.26	212	1993–94	0.14	0.25	341
1988–89	0.58	0.22	310	1994–95	0.13	0.27	172
1989–90	0.61	0.22	236	1995–96	0.51	0.33	37
1990–91	0.76	0.23	238	1996–97	0.41	0.26	104

The standardised analysis for the CELR data used daily catch in a linear regression model. Indices from this model (Table 4, Figure 2) show a steep decline for the first four years, followed by an increase to a peak in 1995–96, and subsequent low catch rates after then.

Table 4: Standardised CPUE indices (relative year effect) based on CELR data with number of days from 1990–91 to 2005–06.

Year	CPUE index	CV	Number of days	Year	CPUE index	CV	Number of days
1990–1991	2.17	0.27	110	1999–2000	0.34	0.27	131
1991–1992	1.11	0.27	108	2000–2001	0.34	0.28	88
1992–1993	0.74	0.27	126	2001–2002	0.33	0.28	73
1993–1994	0.28	0.28	81	2002–2003	0.61	0.26	67
1994–1995	0.53	0.30	46	2003–2004	0.59	0.25	75
1995–1996	1.16	0.33	29	2004–2005	0.35	0.24	114
1996–1997	0.53	0.38	19	2005–2006	0.36	0.26	80
1997–1998	0.36	0.30	52				
1998–1999	0.39	0.28	112				

Figure 2: The CPUE indices based on: (i) TCEPR data (solid line and crosses) covering 1985–86 to 1996–97, and (ii) CELR data (triangles and dashed line) covering 1990–91 to 2005–06. The CELR index has been scaled so that it has the same mean value as the TCEPR index in the years that they overlap.

3.2 Biomass estimates

No estimates of current biomass are available. Based on previous stock assessments using CPUE data the TACC was cut back severely from about 1700 t in 1994–95 to 110 t in 2000–01. By the late 1990s the stock was believed to be well below B_{MSY} where it continued until at least 2004 (17% B_0 in the 2004 assessment, Figure 3). Despite the large reduction in annual removals from the stock after 2001–02, catch rates did not increase over the subsequent 5 years.

An updated assessment was attempted in 2007 with the addition of catch data up to 2005–06 and new standardised CPUE indices (Figure 2) based on TCEPR data (1986 to 1997) and a separate CELR series (1991 to 2006). These data were incorporated in a Bayesian stock assessment with deterministic recruitment to estimate stock size. The Working Group rejected the assessment on the basis of the poor fit to the recent CPUE data. The model was insensitive to the recent CPUE data and predicted a rebuild (driven by the recruitment assumptions) that is not supported by any observations in the fishery.

Figure 3: Biomass trajectory derived from Maximum Posterior Density (MPD) estimate of the model parameters (2004 stock assessment). The biomass trajectory is shown by the solid line; crosses denote the CPUE index scaled to biomass.

4. STATUS OF THE STOCK

Stock Structure Assumptions

The ORH 7B stock has been treated as a single spawning stock located around the Cook Canyon area. It is assessed and managed separately from other stocks and is assumed to be non-mixing with orange roughy stocks outside of the Cook Canyon area.

Stock Status	
Year of Most Recent Assessment	2004
Assessment Runs Presented	One base case
Reference Points	Target: 30% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: -
Status in relation to Target	B_{2004} was estimated to be 17% B_0 , Very Unlikely (< 10%) to be at or above the target
Status in relation to Limits	B_{2004} was Likely (> 60%) to be below the Soft Limit and Unlikely (< 40%) to be below the Hard Limit

Historical Stock Status Trajectory and Current Status

Biomass trajectory derived from Maximum Posterior Density (2004 stock assessment model)

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Unknown, but biomass is thought to be very low.
Recent Trend in Fishing Mortality or Proxy	The fishery has been effectively closed since October 2007.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis (2004)

Stock Projections or Prognosis	Stable at current catch level
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Already below the Soft Limit Hard Limit: Very Unlikely (< 10%)

ORANGE ROUGHY (ORH 7B)

Assessment Methodology and Evaluation		
Assessment Type	Type 1 - Quantitative stock assessment	
Assessment Method	Age-structured model with Bayesian estimation of posteriors.	
Assessment Dates	Latest assessment: 2004	Next assessment: Unknown
Overall assessment quality rank	-	
Main data inputs (rank)	- Catch history - CPUE indices (1985–2003)	
Data not used (rank)	-	
Changes to Model Structure and Assumptions	- CPUE indices based on mean catch per hour as opposed to previous measure of mean catch per tow	
Major Sources of Uncertainty	- Recruitment assumed to be deterministic - CPUE assumed to be directly proportional to stock biomass in base model	

Qualifying Comments (2010)

A further assessment was attempted in 2007 with updated information; however, this was rejected by the working group as the model was insensitive to the CPUE data. The model indicated that the stock had been rebuilding since the mid 1990s, a trend not supported by any observations in the fishery. The fishery was closed from 1 October 2007 and stock size is expected to increase.

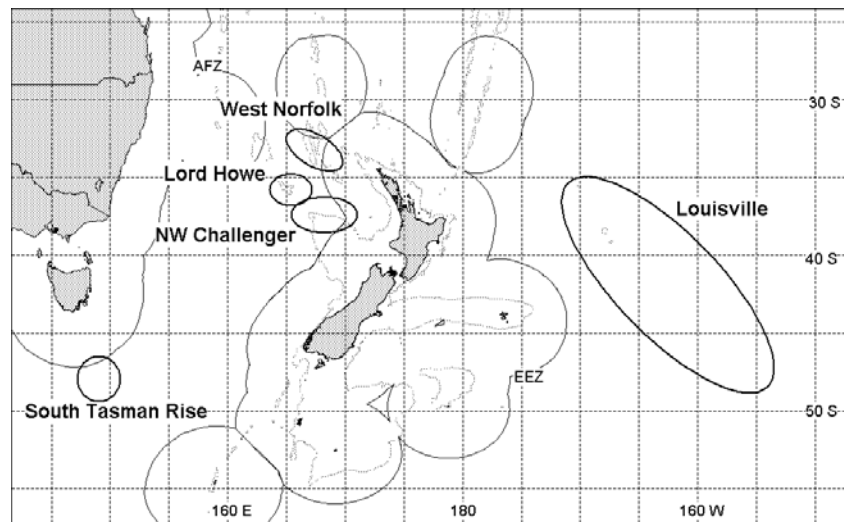

Fishery Interactions

Historically, the main bycatch species were oreos and deepwater dogfish. Other bycatch species recorded include deepwater sharks, deepsea skates, seabirds and corals. The fishery is currently closed.

ORANGE ROUGHY OUTSIDE THE EEZ (ORH ET)

1. FISHERY SUMMARY

1.1 Commercial fisheries

Fisheries outside the EEZ in the New Zealand region occur on ridge systems and seamount chains in the Tasman Sea and southwest Pacific Ocean. There are five main fishing areas: Lord Howe Rise, Northwest Challenger Plateau, West Norfolk Ridge, South Tasman Rise, and Louisville Ridge (see figure above).

Fisheries outside the EEZ developed firstly on the “Westpac Bank” close to the main fishing grounds on the southwest Challenger Plateau in the early-mid 1980s. This is included in the stock area of ORH 7A, and so is not covered here. Further exploration in the region resulted in the development of commercial fisheries on the Lord Howe Rise in 1987–88, Northwest Challenger Plateau in 1988–89, Louisville Ridge in 1993–94, South Tasman Rise in 1997–98, and West Norfolk Ridge in 2001–02 (Table 1).

Table 1: Estimated catches (t) of orange roughy for ORH ET fisheries from 1987–88 to 2006–07. (Data from New Zealand (FSU, QMS), Australia (AFMA), and various sources for other countries. Note that the fishing year for South Tasman Rise is March to February, all others are October to September).

Fishing year	Lord Howe	NW Challenger	Louisville	West Norfolk	South Tasman	Total ET
1987–88	4 000	5	0	0	0	4 005
1988–89	2 430	297	0	0	0	2 727
1989–90	927	425	0	0	0	1 352
1990–01	282	123	0	0	0	405
1991–02	859	620	0	0	0	1 479

2006–07	40	96	323	552	0	1 011

Catch totals include data from New Zealand and Australian vessels available from tow by tow fishing records, with estimated catches added for vessels from Japan, USSR, Korea, Norway, South Africa and China. Catch statistics are likely to be incomplete.

ORANGE ROUGHY (ORH ET)

These fisheries were historically unregulated, with the exception of the South Tasman Rise area, where catches by Australian and New Zealand vessels have at times been restricted by a TAC imposed under a Memorandum of Understanding between the two countries. The South Tasman Rise fishery is currently closed.

South Pacific Regional Fisheries Management Organisation (SPRFMO) Convention Area

Regulation of these fisheries was implemented following adoption of the SPRFMO interim measures in May 2007, and specific high sea fishing permits for the SPRFMO Area have been issued since 2007–08. Table 2 shows the number of New Zealand vessels that fished and their orange roughy catch by area. Since 2007, an orange roughy catch limit has been applied for New Zealand vessels, being the average annual catch between 2002 and 2006 (1852 t). Australia implements analogous limits for its vessels based on average catches between 2002 and 2006, and no other nations are currently fishing.

Table 2: Annual catch (t) and effort data for orange roughy from New Zealand vessels for the SPRFMO Area (calendar years). Westpac Bank is on the Challenger Plateau but is considered part of the straddling stock ORH 7A so landings from that area are tabulated separately. Australian catches over this period, mostly from the Tasman Sea, ranged from 0 to 148 t, mean 46 t per annum). No other nations fished.

Year	Number of Vessels	Number of tows	Lord Howe	NW Challenger	Westpac	Louisville	West Norfolk	Other	All areas
2007	8	415	34	36	-	280	515	-	866
2008	4	208	380	31	-	-	426	-	837
2009	6	545	403	238	23	-	233	31	928
2010	7	1 170	385	415	5	584	79	6	1 474
2011	7	1 158	1	675	5	285	113	-	1 079
2012	6	652	121	247	8	288	49	8	721
2013	5	760	344	230	3	565	19	3	1 164
2014	5	403	79	57	54	754	-	54	998
2015	5	959	157	530	118	462	20	-	1 287
2016	6	943	208	486	234	27	-	-	954

The SPRFMO Convention was closed for signature in January 2011 and formally entered into force in August 2012. Since that time, monitoring and assessment of catches and fisheries, including for orange roughy, has been overseen by the SPRFMO Scientific Committee.

South Tasman Rise

Exploratory fishing south of Tasmania located aggregations of orange roughy on the South Tasman Rise just outside the Australian Fishing Zone (AFZ) in late 1997. The fishery rapidly increased in the next four years (Table 3), with Australian and New Zealand vessels working several small hill features on the Rise. However, New Zealand vessels have not fished the South Tasman Rise since 2000–01. Effort dropped continuously from 2001–02, and mean catch per tow in 2004–05 was about 1 t/tow. Note that insufficient vessels have fished since 2005–06 to enable presentation of catch or effort summaries.

Table 3: Catch and effort data from the South Tasman Rise (combined Australian and New Zealand data).

Fishing year	Number of tows	Total recorded catch (t)	Mean tow length (h)	Mean catch rate (t/tow)	Mean catch rate (t/h)
1996–97	61	4	0.6	0.1	0.5
1997–98	1 132	3 930	0.7	3.5	17.4
1998–99	1 332	1 705	0.6	1.3	10.4
1999–00	1 086	3 360	0.5	3.1	21.1
2000–01	1 155	830	0.4	0.7	6.7
2001–02	201	170	0.8	1.0	3.5
2002–03	164	110	0.5	0.9	7.9
2003–04	67	2	0.3	0.1	0.4
2004–05	47	55	0.3	1.2	14.7

The fishery was formally regulated by a Memorandum of Understanding between Australia and New Zealand from December 1998. A precautionary TAC of 2100 t was applied, increased to 2400 t in 2000–01, and then progressively reduced to 600 t for 2004–05. The fishery was closed to all trawling in 2007.

1.2 Summary of trends in commercial fisheries

Information presented to the SPRFMO Scientific Committee shows that New Zealand catches of orange roughy have declined since the early 2000s and have been relatively stable at about 1000 t since about 2006 (Figure 1). This is well below the catch limit of 1 852 t. The distribution of catches between areas has varied substantially.

Figure 1: Reported catch by area by New Zealand vessels, 2002–2016.

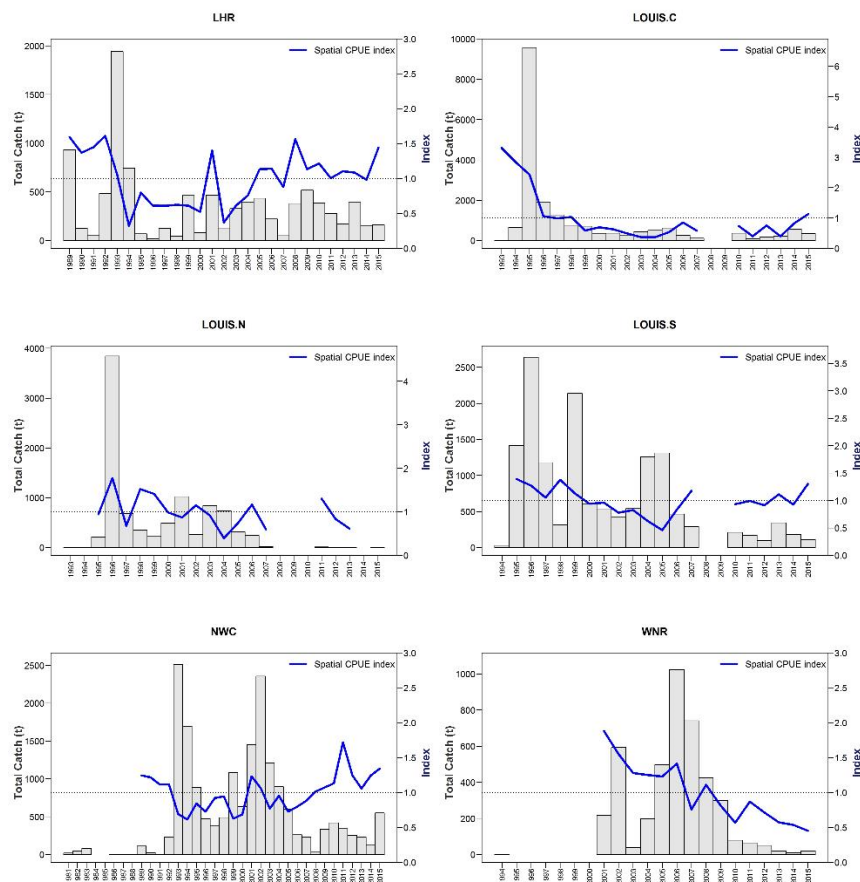

Figure 2: Spatial CPUE indices from Roux & Edwards (2017) for the six orange roughy management areas considered in stock assessments presented to the SPRFMO Scientific Committee in 2017, with annual catch series (histograms).

ORANGE ROUGHY (ORH ET)

Catch rates have varied considerably. Roux and Edwards (2017) developed a spatially-disaggregated CPUE index of stock abundance that corrects for some of the known issues with CPUE for orange roughy (Figure 2). This index shows less variability between years than unstandardized or standard GLM modelled-CPUE, but it is still not known whether it indexes biomass.

1.3 Recreational fisheries

There is no non-commercial fishery for orange roughy in these areas.

1.4 Customary non-commercial fisheries

There is no customary non-commercial fishing for orange roughy in these areas.

1.5 Illegal catch

In most of these areas, there were no regulations regarding limits on catch in international waters before 2007. The South Tasman Rise region has been subject to catch restrictions for Australian and New Zealand vessels under a Memorandum of Understanding between the two countries. In 1999–2000 vessels registered in South Africa and Belize fished the region. The estimated catch of at least 750 t has been included in the catch total for that year. No other information is available on any possible illegal catch on the South Tasman Rise, or the Westpac Bank part of ORH 7A.

1.6 Other sources of mortality

There may be some overrun of reported catch because of fish loss with trawl gear damage, ripped nets, discards, and conversion factor inaccuracies. In a number of other orange roughy fisheries, a current level of 5% has been applied (higher in the past). No corrections are made here because of limited information on the sources which may differ with each fishery.

2. STOCKS AND AREAS

Stock structure is uncertain but Clark et al (2016) analysed multiple data sets and recommended that fishing grounds in the following areas be considered as separate units for the purpose of stock assessment: Lord Howe Rise; NW Challenger; SW Challenger; West Norfolk Ridge; South Tasman Rise, and North, Central, and South Louisville (Figure 3).

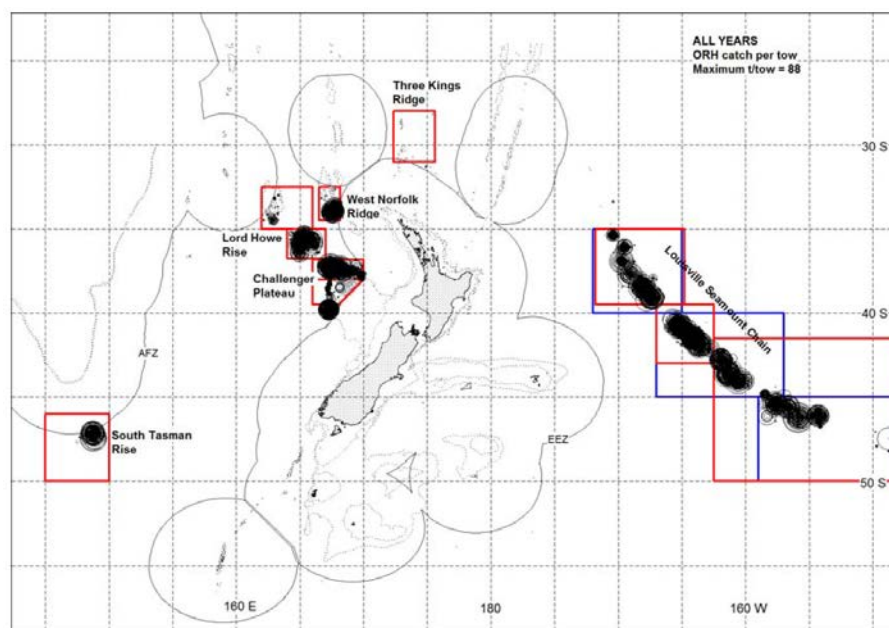

Figure 3: Comparison of new areas assumed for stock assessment purposes (in red) and previous areas (in blue) overlaid on the total distribution of catch rates for orange roughy. Where both areas are coincident, red boxes overlay blue boxes. See Clark et al 2016 for details.

Orange roughy on the South Tasman Rise are regarded as a straddling stock with fish inside the AFZ. Those on the Westpac Bank on the SW Challenger Plateau are regarded as a straddling stock with fish inside New Zealand's EEZ and the ORH 7A stock.

3. STOCK ASSESSMENT

Several low-information stock assessments were presented to the SPRFMO Scientific Committee in 2015 and 2016 but these were not used by the committee to frame advice to the SPRFMO Commission until the 2017 meeting. The following is an extract from the report of the Scientific Committee's meeting in August 2017.

98. *Noting the urgent need to collect information to support robust assessments of orange roughy in the SPRFMO Area for sound management advice, the Scientific Committee considered the three approaches to assess SPRFMO orange roughy stocks as detailed in SC5-DW11 to DW14, SC5-INF03, and the Report of the 2nd Deepwater Workshop of the Scientific Committee (Annex 5). Although none of the methods is ideal for the assessment of SPRFMO orange roughy stocks, the SC considered them to be collectively indicative of stock status and potential yields. The development of advice on catch limits for individual stocks was considered but, because of the level of uncertainty in estimates of status and yield by stock, it was considered better to group the stocks for the development of advice.*
99. *The SC used the lower 95% CIs of estimated stock status to inform the level of precaution that might be appropriate. The group of stocks to the west of New Zealand (in the Tasman Sea) have a greater potential for low stock status than those to the east (Louisville Ridge) and a more precautionary approach was considered appropriate there.*

Papers adopted and cited by the Scientific Committee in framing this advice were as follows:

- Roux et al (2017), FAR 2017/01, tabled as paper SC5-DW11: Low information stock assessment of orange roughy in the SPRFMO Area. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-DW11-NZFAR-2017-01-Orange-roughy-SPRFMO-area.pdf>
- Edwards & Roux (2017), tabled as paper SC5-DW12: A simple delay-difference model for assessment of data-poor orange roughy stocks. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-DW12-Edwards-Roux-Delay-difference-ORY-model.pdf>
- Roux & Edwards (2017), tabled as paper SC5-DW13: A data limited approach for assessing small scale fisheries for orange roughy in the SPRFMO Area. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-DW13-rev1-Roux-Edwards-BDM-method-ORY.pdf>
- Cordue (2017a), tabled as paper SC5-DW14: Catch-history based stock assessments of seven SPRFMO orange roughy stocks. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-DW14-Cordue-catch-history-method-ORY.pdf>
- Cordue (2017b), tabled as paper SC5-INF03: A CPUE based stock assessment of the Louisville Central orange roughy stock. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-INF03-LouisCentralAssess.pdf>
- Galvez et al (2017), tabled as paper SC5-Doc08: Report from the Deepwater Workshop in Hobart, May 2017. Available at: <http://www.sprfmo.int/assets/SC5-2017/SC5-Doc08-rev1-DWG-Workshop-Report-Final27Sep17.pdf>

4. STATUS OF THE STOCKS

The status of the stocks in the SPRFMO Convention Area is poorly known. The SPRFMO Scientific Committee based its precautionary advice to the Commission in 2017 on the papers cited in Section 3, using the lower limit of 95% confidence or credible intervals of the estimated status from a range of low-information methods. These were tabulated by Cryer et al (2017) (Table 4).

It is not known if recent catch levels are sustainable, or whether they will allow the stocks to move towards a size that will support the *MSY*.

Table 4: Summary results from biomass dynamic modelling using a spatially disaggregated CPUE index (BDM) and catch-history age-structured assessment (CAS) for seven putative stocks of orange roughy. The lower 95% credible limits of depletion are from Roux & Edwards 2017 (BDM) and Cordue 2017a (CAS) and potential yield is here estimated as $B_{curr} \times HR_{MSY}$ (BDM) and the lower limit of Cordue’s illustrative range of percentiles from the posterior distribution of long-term yield (CAS).

Management unit	Lower 95% CI from BDM	Potential Yield from BDM (t)	Lower 95% CI from CAS	Potential Yield from CAS (t)
Louisville North	0.35	207	0.32	270
Louisville Central*	0.14	148	0.24	400
Louisville South	0.39	510	0.18	270
West Norfolk Ridge	0.26	60	0.19	110
Lord Howe Rise**	0.49	N/A	0.07	87
Northwest Challenger	N/A	N/A	0.13	170
South Tasman Rise	N/A	N/A	0.42	N/A

* An age-structured CPUE model for Louisville Central (Cordue 2017b) gave estimates of the lower 95% limits for depletion and yield intermediate between those of BDM and CAS models.

** The BDM fit for Lord Howe Rise included an implausibly high estimate of r_{max} for orange roughy and the model was not considered useful.

OREOS (OEO)

(*Pseudocyttus maculatus*, *Allocyttus niger*, *Neocyttus rhomboidalis* and *Allocyttus verucosus*)

1. INTRODUCTION

The oreo (OEO) complex consists of four species: smooth oreo (*Pseudocyttus maculatus*; SSO), black oreo (*Allocyttus niger*; BOE), spiky oreo (*Neocyttus rhomboidalis*; SOR) and warty oreo (*Allocyttus verucosus*; WOE). The species most commonly caught are smooth oreo and black oreo.

The main black oreo and smooth oreo fisheries have been assessed separately and individual reports produced for each as follows:

1. OEO 3A black oreo and smooth oreo
2. OEO 4 black oreo and smooth oreo
3. OEO 1 and OEO 6 black oreo and smooth oreo

2. BIOLOGY

2.1 Black oreo

Black oreo have been found within a 600 m to 1300 m depth range. The geographical distribution south of about 45° S is not well known. It is a southern species and is abundant on the south Chatham Rise, along the east coast of the South Island, the north and east slope of Pukaki Rise, the Bounty Platform, the Snares slope, Puysegur Bank and the northern end of the Macquarie Ridge. They most likely occur all around the slope of the Campbell Plateau.

Spawning occurs from late October to at least December and is widespread on the south Chatham Rise. Mean length at maturity for females, estimated from Chatham Rise trawl surveys (1986–87, 1990, 1991–93) using macroscopic gonad staging, is 34 cm TL.

They appear to have a pelagic juvenile phase, but little is known about this phase because only about 12 fish less than 21 cm TL have ever been caught. The pelagic phase may last for 4–5 years with lengths of up to 21–26 cm TL.

Unvalidated age estimates were obtained for Chatham Rise and Puysegur-Snares samples in 1995 and 1997 respectively using counts of the zones (assumed to be annual) observed in thin sections of otoliths.

OREOS (OEO)

These estimates indicate that black oreo is slow growing and long lived. The maximum estimated age was 153 years (45.5 cm TL fish). Australian workers used the same methods, i.e., sections of otoliths, and reported similar results. A von Bertalanffy growth curve was fitted to the Puysegur samples only (Table 1). Estimated age at maturity for females was 27 years.

A first estimate of natural mortality (M), $0.044 \text{ (yr}^{-1}\text{)}$, was made in 1997 using the Puysegur growth data only. This estimate is uncertain because it appeared that the otolith samples were taken from a well fished part of the Puysegur area.

Black oreo appear to settle over a wide range of depths on the south Chatham Rise, but appear to prefer to live in the depth interval 600–800 m that is often dominated by individuals with a modal size of 28 cm TL.

2.2 Smooth oreo

Smooth oreo occur from 650 m to about 1500 m depth. The geographical distribution south of about 45° S is not well known. It is a southern species and is abundant on the south Chatham Rise, along the east coast of the South Island, the north and east slope of Pukaki Rise, the Bounty Platform, the Snares slope, Puysegur Bank and the northern end of the Macquarie Ridge. They most likely occur all around the slope of the Campbell Plateau.

Spawning occurs from late October to at least December and is widespread on the south Chatham Rise in small aggregations. Mean length at maturity for females, estimated from Chatham Rise trawl surveys (1986–87, 1990, 1991–93) using macroscopic gonad staging, is 40 cm TL.

They appear to have a pelagic juvenile phase, but little is known about this phase because only about six fish less than 16 cm TL have ever been caught. The pelagic phase may last for 5–6 years with lengths of up to 16–19 cm TL.

Unvalidated age estimates were obtained for Chatham Rise and Puysegur-Snares fish in 1995 and 1997 respectively using counts of the zones (assumed to be annual) observed in thin sections of otoliths. These estimates indicate that smooth oreo is slow growing and long lived. The maximum estimated age was 86 years (51.3 cm TL fish). Australian workers used the same methods, i.e., sections of otoliths, and reported similar results. A von Bertalanffy growth curve was fitted to the age estimates from Chatham Rise and Puysegur-Snares fish combined and the parameters estimated for the growth curve are in Table 1. Estimated age at maturity for females was 31 years.

An estimate of natural mortality, $0.063 \text{ (yr}^{-1}\text{)}$, was made in 1997 (Doonan et al 1997). The estimate was from a moderately exploited population of fish from the Puysegur region.

There are concentrations of recently settled smooth oreo south and south west of Chatham Island, although small individuals (16–19 cm TL) occur widely over the south Chatham Rise at depths of 650–800 m.

Table 1: Biological parameters for black oreo and smooth oreo stock assessments. Values not estimated are indicated by (-). Some parameters may be estimated in specific stock assessments. [Continued on next page.]

3. STOCKS AND AREAS

3.1 Black oreo

Stock structure of Australian and New Zealand samples was examined using genetic (allozyme and mitochondrial DNA) and morphological counts (fin rays, etc.). It was concluded that the New Zealand samples constituted a stock distinct from the Australian sample based on “small but significant difference in mtDNA haplotype frequencies (with no detected allozyme differences), supported by differences in pyloric caeca and lateral line counts”. The genetic methods used may not be suitable tools for stock discrimination around New Zealand.

A New Zealand pilot study examined stock relationships using samples from four management areas (OEO 1, OEO 3A, OEO 4 and OEO 6) of the New Zealand EEZ. Techniques used included genetic (nuclear and mitochondrial DNA), lateral line scale counts, settlement zone counts, parasites, otolith microchemistry, and otolith shape. Lateral line scale and pyloric caeca counts were different between samples from OEO 6 and the other three areas. The relative abundance of three parasites differed significantly between all areas. Otolith shape from OEO 3A samples was different to that from OEO 1 and OEO 4, but OEO 1, OEO 4 and OEO 6 otolith samples were not morphologically different. Genetic, otolith microchemistry, and settlement zone analyses showed no regional differences.

3.2 Smooth oreo

Stock structure of Australian and New Zealand samples was examined using genetic (allozyme and mitochondrial DNA) and morphological counts (fin rays, etc.). No differences between New Zealand and Australian samples were found using the above techniques. A broad scale stock is suggested by these results but this seems unlikely given the large distances between New Zealand and Australia. The genetic methods used may not be suitable tools for stock discrimination around New Zealand.

A New Zealand pilot study examined stock relationships using samples from four management areas (OEO 1, OEO 3A, OEO 4 and OEO 6) of the New Zealand EEZ. Techniques used included genetic (nuclear and mitochondrial DNA), lateral line scale counts, settlement zone counts, parasites, otolith

OREOS (OEO)

microchemistry, and otolith shape. Otolith shape from OEO 1 and OEO 6 was different to that from OEO 3A and OEO 4 samples. Weak evidence from parasite data, one gene locus and otolith microchemistry suggested that northern OEO 3A samples were different from other areas. Lateral line scale and otolith settlement zone counts showed no differences between areas.

These data suggest that the stock boundaries given in previous assessment documents should be retained until more definitive evidence for stock relationships is obtained, i.e., retain the areas OEO 1, OEO 3A, OEO 4, and OEO 6 (see the figure on the first page of the Oreos assessment report above).

The four species of oreos (black oreo, smooth oreo, spiky oreo, and warty oreo) are managed with separate catch limits for black and smooth in some areas. Each species could be managed separately. They have different depth and geographical distributions, different stock sizes, rates of growth, and productivity.

4. FISHERY SUMMARY

4.1 Commercial fisheries

Commercial fisheries occur for black oreo (BOE) and smooth oreo (SSO). Oreos are managed as a species group, which also includes spiky oreo (SOR). The Chatham Rise (OEO 3A and OEO 4) is the main fishing area, but other fisheries occur off Southland on the east coast of the South Island (OEO 1/OEO 3A), and on the Pukaki Rise, Macquarie Ridge, and Bounty Plateau (OEO 6). In the past oreo catch has been taken as bycatch of the more valuable orange roughy fisheries but target fisheries are now much more common in most areas for smooth or black oreo.

Total reported landings of oreos and TACs are shown in Table 2, while Figure 1 depicts the historical landings and TACC values for the main OEO stocks. OEO 3A and OEO 4 were introduced into the QMS in 1982–83, while OEO 1 and OEO 6 were introduced later in 1986–87. Total oreo catch from OEO 4 exceeded the TAC from 1991–92 to 1994–95 and was close to the TAC from 1995–96 to 2000–01 (Table 2). Catch remained high in OEO 4 while the orange roughy fishery has declined. The OEO 4 TACC was reduced from 7 000 to 5 460 t in 2001–02 but was restored to 7 000 t in 2003–04. In 2015–16, following an assessment of SSO 4, the OEO 4 TACC was reduced to 3 000 t and the catch of smooth oreo was approximately 2 000 t.

The oreo catch from OEO 3A was less than the TAC from 1992–93 to 1995–96, substantially so in 1994–95 and 1995–96. The OEO 3A TAC was reduced from 10 106 to 6 600 t in 1996–97. A voluntary agreement between the fishing industry and the Minister of Fisheries to limit catch of smooth oreo from OEO 3A to 1400 t of the total oreo TAC of 6 600 t was implemented in 1998–99. Subsequently the total OEO 3A TAC was reduced to 5 900 t in 1999–00, 4 400 in 2000–01, 4 095 in 2001–02 and 3 100 t in 2002–03. Catch from the Sub-Antarctic area (OEO 6) increased substantially in 1994–95 and exceeded the TAC in 1995–96. The OEO 6 TAC was increased from 3 000 to 6 000 t in 1996–97. There was also a voluntary agreement not to fish for oreos in the Puysegur area which started in 1998–99. OEO 1 was fished under the adaptive management programme up to the end of 1997–98. The OEO 1 TAC reverted back to pre-adaptive management levels from 1998–99. Catches have declined since then, and from 1 October 2007 the TACC was reduced to 2500 t, and other sources of mortality were allocated 168 t.

Reported estimated catches by species from tow by tow data recorded in catch and effort logbooks (Deepwater, TCEPR, and CELR) and the ratio of estimated to landed catch reported are given in Table 3.

Table 2: Total reported landings (t) for all oreo species combined by Fishstock from 1978–79 to present and TACs (t) from 1982–83 to present.

Fishing year	OEO 1		OEO 3A		OEO 4		OEO 6		Totals

Descriptive analyses of the main New Zealand oreo fisheries were updated with data from 2006–07 in 2008. Standardised CPUE analyses of black and smooth oreo have been updated as follows:

- smooth oreo in OEO 3A in 2009;
- black oreo in OEO 4 in 2009;
- black oreo in OEO 6 (Pukaki) in 2009;
- smooth oreo OEO 6 (Bounty) in 2008;
- black oreo in OEO 3A in 2008;
- smooth oreo in OEO 4 in 2007;
- smooth oreo in Southland (OEO 1 and OEO 3A) in 2007;
- smooth oreo OEO 6 (Pukaki) in 2006.

Figure 1: Reported commercial landings and TACC for the four main OEO stocks. From top: OEO 1 (Central East - Wairarapa, Auckland, Central Egmont, Challenger, Southland, South East Catlin Coast), OEO 3A (South East Cook Strait/Kaikoura/Strathallan). [Continued on next page].

Figure 1 [Continued]: Reported commercial landings and TACC for the four main OEO stocks. From top: OEO 4 (South East Chatham Rise), and OEO 6 (Sub-Antarctic).

4.2 Recreational fisheries

There are no known recreational fisheries for black oreo and smooth oreo.

4.3 Customary non-commercial fisheries

There is no known customary non-commercial fishing for black oreo and smooth oreo.

4.4 Illegal catch

Estimates of illegal catch are not available.

4.5 Other sources of mortality

Dumping of unwanted or small fish and accidental loss of fish (lost codends, ripped codends, etc.) were features of oreo fisheries in the early years. These sources of mortality were probably substantial in those early years but are now thought to be relatively small. No estimate of mortality from these sources has been made because of the lack of hard data and because mortality now appears to be small. Estimates of discards of oreos were made for 1994–95 and 1995–96 from MFish observer data. This involved calculating the ratio of discarded oreo catch to retained oreo catch and then multiplying the annual total oreo catch from the New Zealand EEZ by this ratio. Estimates were 207 and 270 t for 1994–95 and 1995–96 respectively.

5. ENVIRONMENTAL AND ECOSYSTEM CONSIDERATIONS

This section was updated for the 2018 Fishery Assessment Plenary. An issue-by-issue analysis is available in the Aquatic Environment & Biodiversity Annual Review 2017 (MPI 2017, <https://www.mpi.govt.nz/dmsdocument/27471-aquatic-environment-and-biodiversity-annual-review-aebar-2017-a-summary-of-environmental-interactions-between-the-seafood-sector-and-the-aquatic-environment>).

5.1 Role in the ecosystem

Smooth and black oreo dominate trawl survey relative abundance estimates of demersal fish species at 650–1200 m on the south and southwest slope of the Chatham Rise (e.g., Hart & McMillan 1998). They are probably also dominant at those depths on the southeast slope of the South Island and other southern New Zealand slope areas including Bounty Plateau, and Pukaki Rise. They are replaced at depths of about 700–1200 m on the east and northern slope of Chatham Rise by orange roughy. The south Chatham Rise oreo fisheries are relatively long-standing, dating from Soviet fishing in the 1970s but the effects of extracting approximately 6 000 t per year of smooth oreo from the south Chatham Rise (OEO 4) ecosystem between 1983–84 and 2012–13 are unknown.

5.1.1 Trophic interactions

Smooth oreo feed mainly on salps (80%), molluscs (9%, of which 8% are squids but also including octopods), and teleosts (5%) (percentage frequency of occurrence in stomachs with food, Stevens et al 2011). Black oreo feed on teleosts (48%), crustaceans (36%), salps (24%), and cephalopods (mainly squid, 6%) (Stevens et al 2011). Diet varies with fish size but salps remained the main prey for smooth oreo in the largest fish with small numbers of Scyphozoa, fish and squids. Salps were the main prey for smaller black oreo but amphipods and natant decapod crustaceans were important for intermediate sized fish (Clark et al 1989). Smooth oreo and black oreo occur with orange roughy at times. Orange roughy diet was mainly crustaceans (58%), teleosts (41%), and molluscs (10%, particularly squids) (frequency of occurrence, Stevens et al 2011) suggesting little overlap with the salp-dominated diet of smooth oreo. Where they co-occur, orange roughy and black oreo may compete for teleost and crustacean prey.

Predators of oreos probably change with fish size. Larger smooth oreo, black oreo and orange roughy were observed with healed soft flesh wounds, typically in the dorso-posterior region. Wound shape and size suggest they may be caused by one of the deepwater dogfishes (Dunn et al 2010).

5.1.2 Ecosystem indicators

Tuck et al (2009) used data from the Sub-Antarctic and Chatham Rise middle-depth trawl surveys to derive indicators of fish diversity, size, and trophic level. However, fishing for oreos occurs mostly deeper than the depth range of these surveys and is only a small component of fishing in the areas considered by Tuck et al (2009).

5.2 Bycatch (fish and invertebrates)

Anderson (2011) summarised the bycatch of oreo trawl fisheries from 1990–91 to 2008–09. Since 2002, oreo species (mainly smooth oreo and black oreo) accounted for about 92% of the total estimated catch from all observed trawls targeting oreos. Orange roughy (3.5%) was the main bycatch species, with no other species or group of species accounting for more than 0.6% of the total catch. Hoki were the next most common bycatch species, followed by rattails, deepwater dogfishes, especially Baxter's dogfish (*Etmopterus baxteri*) and seal shark (*Dalatias licha*), slickheads, and basketwork eel (*Diastobranchius capensis*), all of which were usually discarded. Ling were also frequently caught, but only comprised about 0.3% of the total catch. In total, over 250 species or species groups were identified by observers in the target fishery. Total annual fish bycatch in the oreo fishery since 1990–91 ranged from about 270 t to 2200 t and, apart from some higher levels in the late 1990s, did not show any obvious trends. Bycatch was split almost evenly between commercial and non-commercial species although, since 2002, about 60% of the bycatch was of commercial species.

The main invertebrate bycatch includes corals (almost 0.4% of the total catch, Anderson 2011), squids and octopuses, king crabs, and echinoderms. Tracey et al (2011) analysed the distribution of nine groups of protected corals based on bycatch records from observed trawl effort from 2007–08 to 2009–10,

primarily from 800–1000 m depth. For the oreo target fishery, the highest catches were reported from the north and south slopes of the Chatham Rise, east of the Pukaki Rise, and on the Macquarie Ridge.

5.3 Incidental capture of Protected Species (seabirds, mammals, and protected fish)

For protected species, capture estimates presented here include all animals recovered to the deck of fishing vessels (alive, injured or dead), but do not include any cryptic mortality (e.g., a seabird struck by a warp but not brought on board the vessel, Middleton & Abraham 2007, Brothers et al 2010). Ramm (2011, 2012a, 2012b) summarised observer data for combined bottom trawl fisheries for orange roughy, oreos, cardinalfish and listed annual captures of seabirds, and mammals from 2008–09 to 2010–11.

5.3.1 Marine mammal interactions

Trawlers targeting orange roughy, oreo, and black cardinalfish occasionally catch New Zealand fur seal (which were classified as “Not Threatened” under the NZ Threat Classification System in 2010, Baker et al 2016). Between 2002–03 and 2007–08, there were 14 observed captures of NZ fur seal in orange roughy, oreo, and black cardinalfish trawl fisheries. There has been one observed capture in the period between 2008–09 and 2016–17, during which time the average level of annual observer coverage was 26.7% (Table 4). Corresponding mean annual estimated captures in this period ranged 0–3 (mean 1.25) based on statistical capture models (Thompson et al 2013; Abraham et al 2016). All observed fur seal captures occurred in the Sub-Antarctic region.

Table 4: Number of tows by fishing year and observed and model-estimated total NZ fur seal captures in orange roughy, oreo, and cardinalfish trawl fisheries, 2002–03 to 2016–17. No. Obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows, % inc, percentage of total effort included in the statistical model. Estimates are based on methods described in Abraham et al (2016), available via <https://data.dragonfly.co.nz/psc> . Estimates for 2002–03 to 2015–16 are based on data version 2017v1.

	Tows	No.obs	%ob	Observed		Estimated

2002–03	8 870	1 383	15.6	0	0	3	0–11
2003–04	8 007	1 262	15.8	2	0.2	7	2–23
2004–05	8 419	1 619	19.2	4	0.2	11	4–35
2005–06	8 294	1 361	16.4	2	0.1	8	2–27
2006–07	7 372	2 326	31.6	2	0.1	3	2–7
2007–08	6 728	2 811	41.8	5	0.2	8	5–17
2008–09	6 133	2 374	38.7	0	0	3	0–14
2009–10	6 013	2 135	35.5	0	0	2	0–12
2010–11	4 182	1 206	28.8	0	0	2	0–12
2011–12	3 655	923	25.3	0	0	2	0–9
2012–13	3 097	345	11.1	0	0	0	0–1
2013–14	3 611	435	12	0	0	0	0–2
2014–15	3 811	961	25.2	1	0.1	1	1–2
2015–16	4 085	1 367	33.5	0	0	0	0–2
2016–17	3 971	1 226	30.9	0	0		

5.3.2 Seabird interactions

Annual observed seabird capture rates ranged from 0 to 0.9 per 100 tows in orange roughy, oreo, and cardinalfish trawl fisheries between 2002–03 and 2014–15 (Baird 2001, 2004 a, b, 2005, Baird & Smith 2004, Abraham & Thompson 2009, Abraham et al 2009, Abraham & Thompson 2011, Abraham et al 2016, Abraham & Richard 2017, 2018). Capture rates have fluctuated without obvious trend at this low level. In the 2015–16 fishing year, there were 4 observed captures of birds, and 2 in 2016–17, in orange roughy, oreo, and cardinalfish trawl fisheries at a rate of 0.3 to 0.2 birds (respectively) per 100 observed tows (Table 5). The average capture rate in deepwater trawl fisheries (including orange roughy, oreo and cardinalfish) for the period from 2002–03 to 2015–16 is about 0.29 birds per 100 tows, a very low rate relative to other New Zealand trawl fisheries, e.g. for scampi (4.43 birds per 100 tows) and squid (13.79 birds per 100 tows) over the same years.

Table 5: Number of tows by fishing year and observed seabird captures in orange roughy, oreo, and cardinalfish trawl fisheries, 2002–03 to 2016–17. No. obs, number of observed tows; % obs, percentage of tows observed; Rate, number of captures per 100 observed tows. Estimates are based on methods described in Abraham et al (2016) and Abraham & Richard (2017, 2018) and available via <https://data.dragonfly.co.nz/psc>. Estimates for 2002–03 to 2015–16 are based on data version 2017v1.

	Fishing effort			Observed captures		Estimated captures	
	Tows	No. obs	% obs	Captures	Rate	Mean	95% c.i.
2002–03	8 870	1383	15.6	0	0	29	15–48

Total other birds	-	17	5	0	2	1	0	25
Grand Total		94	18	2	12	2	2	130

Salvin's albatross was the most frequently captured albatross (50% of observed albatross captures) but seven different species have been observed captured since 2002–03. Cape petrels were the most frequently captured other taxon (41%, Table 6). Seabird captures in the orange roughy, oreo, and cardinalfish fisheries have been observed mostly around the Chatham Rise and off the east coast South Island. These numbers should be regarded as only a general guide on the distribution of captures because the observer coverage is not uniform across areas and may not be representative.

The deepwater trawl fisheries (including the cardinal fish target fishery) contributes to the total risk posed by New Zealand commercial fishing to seabirds (see Table 7). The two species to which the fishery poses the most risk are Chatham Island albatross and Salvin's albatross, with this suite of fisheries posing 0.6 and 0.022 of Population Sustainability Threshold (PST) (Table 7). Chatham albatross and Salvin's albatross were assessed at high risk (Abraham et al 2016).

Table 7: Risk ratio of seabirds predicted by the level two risk assessment for the oreo and all fisheries included in the level two risk assessment, 2006–07 to 2016–17, showing seabird species with a risk ratio of at least 0.001 of PST (from Richard et al 2017, where full details of the risk assessment approach can be found). The risk ratio is an estimate of aggregate potential fatalities across trawl and longline fisheries relative to the PST. The DOC threat classifications are shown (Robertson et al 2017 at <http://www.doc.govt.nz/documents/science-and-technical/nztcs19entire.pdf>).

Species name	PST (mean)	Risk ratio		Risk category	DOC Threat Classification
		OEO, ORH, CDL target trawl	TOTAL		
Chatham Island albatross	425.2	0.060	0.362	High	At Risk: Naturally Uncommon
Salvin's albatross	3 599.5	0.022	0.780	High	Threatened: Nationally Critical
Northern giant petrel	335.4	0.005	0.138	Medium	At Risk: Naturally Uncommon
Northern Buller's albatross	1 627.4	0.002	0.253	Medium	At Risk: Naturally Uncommon
Black petrel	437.1	0.002	1.153	Very high	Threatened: Nationally Vulnerable
Antipodean albatross	364.3	0.002	0.203	Medium	Threatened: Nationally Critical
Gibson's albatross	496.1	0.002	0.337	High	Threatened: Nationally Critical
Northern royal albatross	715.1	0.001	0.043	Low	At Risk: Naturally Uncommon

Mitigation methods such as streamer (tori) lines, Brady bird bafflers, warp deflectors, and offal management are used in the orange roughy, oreo, and cardinalfish trawl fisheries. Warp mitigation was voluntarily introduced from about 2004 and made mandatory in April 2006 (Department of Internal Affairs 2006). The 2006 notice mandated that all trawlers over 28 m in length use a seabird scaring device while trawling (being “paired streamer lines”, “bird baffle” or “warp deflector” as defined in the Notice).

5.4 Benthic interactions

Orange roughy, oreos, and cardinalfish are taken using bottom trawls and accounted for about 14% of all tows reported on TCEPR forms to have been fished on or close to the bottom between 1989–90 and 2004–05 (Baird et al 2011). Black et al (2013) estimated that, from 2006–07 to 2010–11, 97% of oreo catch was reported on TCEPR forms. Tows are located in Benthic Optimised Marine Environment Classification (BOMECE, Leathwick et al 2009) classes J, K (mid-slope), M (mid-lower slope), N, and O (lower slope and deeper waters) (Baird & Wood 2012), and 94% were between 700 and 1 200 m depth (Baird et al 2011). Deepsea corals in the New Zealand region are abundant and diverse and, because of their fragility, are at risk from anthropogenic activities such as bottom trawling (Clark & O'Driscoll 2003, Clark & Rowden 2009, Williams et al 2010). All deepwater hard corals are protected under Schedule 7A of the Wildlife Act 1953. Baird et al (2012) mapped the likely coral distributions using predictive models, and concluded that the fisheries that pose the most risk to protected corals are these deepwater trawl fisheries.

Trawling for orange roughy, oreo, and cardinalfish, like trawling for other species, is likely to have effects on benthic community structure and function (e.g., Rice 2006) and there may be consequences for benthic productivity (e.g., Jennings et al 2001, Hermesen et al 2003, Hiddink et al 2006, Reiss et al 2009). These consequences are not considered in detail here but are discussed in the Aquatic Environment and Biodiversity Annual Review (Ministry for Primary Industries 2015).

The New Zealand EEZ contains 17 Benthic Protection Areas (BPAs) that are closed to bottom trawl fishing and include about 52% of all seamounts over 1500 m elevation and 88% of identified hydrothermal vents.

5.5 Other considerations

5.5.1 Spawning disruption

Fishing during spawning may disrupt spawning activity or success. Morgan et al (1999) concluded that Atlantic cod (*Gadus morhua*) “exposed to a chronic stressor are able to spawn successfully, but there appears to be a negative impact of this stress on their reproductive output, particularly through the production of abnormal larvae”. Morgan et al (1997) also reported that “Following passage of the trawl, a 300-m-wide “hole” in the [cod spawning] aggregation spanned the trawl track. Disturbance was detected for 77 min after passage of the trawl.” There is no research on the disruption of spawning smooth oreo and black oreo by fishing in New Zealand, but spawning of both species appears to be over a protracted period (October to February) and over a wide area (O’Driscoll et al 2003). Fishing continues during the spawning period, possibly because localised spawning schools of smooth oreo, in particular, may provide good catch rates.

5.5.2 Genetic effects

Fishing, environmental changes, including those caused by climate change or pollution, could alter the genetic composition or diversity of a species. There are no known studies of the genetic diversity of smooth or black oreo from New Zealand. Genetic studies for stock discrimination are reported under “stocks and areas”.

5.5.3 Habitat of particular significance to fisheries management

Habitat of particular significance for fisheries management does not have a policy definition currently although work is currently underway to generate one. O’Driscoll et al (2003) identified the south Chatham Rise as important for smooth oreo spawning, and the north, east and south slope as important for juveniles. The south Chatham Rise is also important for black oreo spawning and juveniles. Deepsea corals such as the reef-forming scleractinian corals and gorgonian sea fan corals are thought to provide prey and refuge for deep-sea fish (Fosså et al 2002, Stone 2006, Mortensen et al 2008). Large aggregations of deepwater species like orange roughy, oreos, and cardinalfish occur above seamounts with high densities of such “reef-like” taxa, but it is not known if there are any direct linkages between the fish and corals. Bottom trawling for orange roughy, oreos, and cardinalfish has the potential to affect features of the habitat that could qualify as habitat of particular significance to fisheries management.

OREOS — OEO 3A BLACK ORO AND SMOOTH ORO

1. FISHERY SUMMARY

This is presented in the Fishery Summary section at the beginning of the Oreos report.

2. BIOLOGY

This is presented in the Biology section at the beginning of the Oreos report.

3. STOCKS AND AREAS

This is presented in the Stocks and Areas section at the beginning of the Oreos report.

4. STOCK ASSESSMENT

The smooth oro stock assessment is unchanged from 2009. The black oro stock assessment for 2008 has been withdrawn but the CPUE series has been updated to 2012.

4.1 Introduction

The following assumptions were made in the stock assessment analyses to estimate biomasses and yields for black oro and smooth oro.

- (a) The acoustic abundance estimates were unbiased absolute values.
- (b) The CPUE analyses provided indices of abundance for either black oro or smooth oro in the whole of OEO 3A. Most of the oro commercial catches came from the CPUE study areas. Research trawl surveys indicated that there was little habitat for, and biomass of, black oro or smooth oro outside those areas.
- (c) The ranges used for the biological values covered their true values.
- (d) The maximum fishing mortality (F_{MAX}) was assumed to be 0.9, varying this value from 0.5 to 3.5 altered B_0 for smooth oro in OEO 3A by only about 6% in the 1996 assessment.
- (e) Recruitment was deterministic and followed a Beverton and Holt relationship with steepness of 0.75.
- (f) Catch overruns were 0% during the period of reported catch.
- (g) The populations of black oro and smooth oro in OEO 3A were discrete stocks or production units.
- (h) The catch histories were accurate.

4.1.1 Black oro

The last accepted assessment was in 2008. A three-area population model was used to accommodate the structure of the catch and length data, with age-dependent migration between areas. However, new age data collected within each area suggest that, based on 2013 analyses, assumptions made by this model are incorrect. Specifically, differences in the size distribution between areas now seem likely to be due to differential growth rates, rather than to movement. The model applied in 2008 was therefore considered inadequate and has been withdrawn. No stock assessment is presented here; a new approach needs to be developed.

4.1.2 Smooth oro

A new assessment of smooth oro in OEO 3A was completed in 2009. This used a CASAL age-structured population model employing Bayesian methods. Input data included research and observer-collected length data, one absolute abundance estimate from a research acoustic survey carried out in 1997 (TAN9713), and three relative abundance indices from standardised catch per unit effort analyses.

4.2 Black oreo

Partition of the main fishery into 3 areas

The main fishery area was split into three areas: a northern area that contained small fish and was generally shallow (Area 1), a southern area that contained large fish in the period before 1993 and which was generally deeper (Area 3), and a transition area (Area 2) that lay between Areas 1 and 3 (Figure 1).

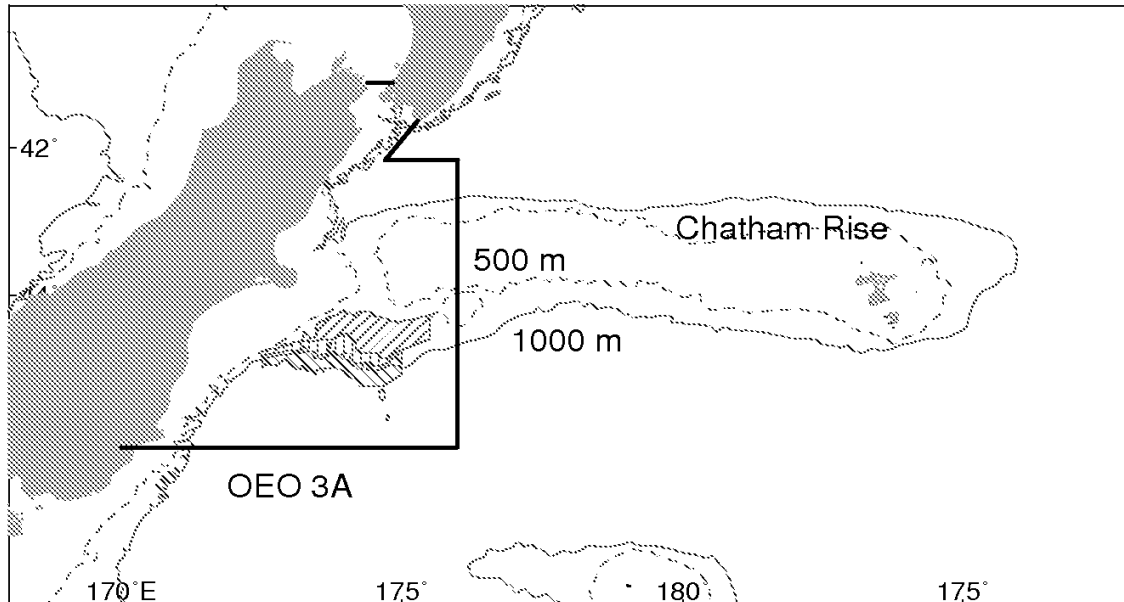

Figure 1: The three spatial areas used in the CASAL model and 2002 acoustic abundance survey. Area 1 at the top with right sloping shading; Area 2 in the middle with vertical shading; Area 3 at the bottom with left sloping shading. The thick dark line encloses management area OEO 3A.

The boundary between Areas 1 and 2 was defined in terms of the northern edge of the area that enclosed 90% of the total catch from the fishery. Areas 2 and 3 contained most of the fishery while Area 1 consisted of lightly fished and unfished ground. The boundary between Areas 2 and 3 was defined by the 32.5 cm contour in mean fish length for data before 1993 so that the fishery is split into an area containing smaller fish and another that has larger fish. The population outside the main fishery was assumed to follow the same relative dynamics.

Rejection of spatial model based on migration

The previous model reconciled the differences in commercial length distribution by using three areas. No age data were incorporated and instead lengths were used as a proxy for age. The dynamics were assumed to be recruitment in the shallow area (Area 1), with migration from Area 1 to Area 2, and also from Area 2 to Area 3, i.e., a one way movement to generally deeper water. The differences in the length distributions between areas drove the estimated migration rates by age. The stock assessment predicted that mature fish in the relatively unfished area (Area 1) comprised about 25% B_0 and so there were no sustainability concerns as this area was largely not fished.

To test the above migration hypothesis, otoliths sampled from acoustic survey mark identification trawls were aged and age distributions estimated for Area 1 and for the combined Areas 2 and 3 (Doonan, pers. comm.). The results showed deficiencies in the use of length data as a proxy for age in the stock assessment model. The age frequency in Area 1 was similar to that from Areas 2 and 3, but the model predicted them to be very different. Growth in Areas 2 and 3 appears to be faster than in Area 1 and this may drive the observed differences in length distributions. The migration model assumed the same growth in all areas. Maturity may be related to length rather than age, but it is age-based in the model. For these reasons, the Working Group rejected the stock assessment model in 2013. No formal stock assessment is presented here.

4.2.1 Estimates of fishery parameters and abundance

Catches by area

Catches were partitioned into the three areas by scaling up the estimated catch of black oreo from each area to the total reported catch (see tables 2 and 3 in the Fishery Summary section at the beginning of the Oreos report) and are given in Table 1.

Table 1: Estimated black oreo catch (tonnes) for each fishing year in the three spatial model areas.

Year	Area 1	Area 2	Area 3	Total
1972–73	110	2 010	1 320	†3 440

† Soviet catch, assumed to be mostly from OEO 3A and to be 50:50 black oreo: smooth oreo.

Observer length frequencies by area

Catch at length data collected by observers in Areas 1, 2, and 3 were extracted from the *obs_lfs* database (Table 2). Derived length frequencies for each group were calculated from the sample length frequencies weighted by the catch weight of each sample.

Table 2: Number of observed commercial tows where black oreo was measured for length frequency. A total of 60 tows were excluded because they had fewer than 30 fish measured, extreme mean lengths or missing catch information.

Year	Area 1	Area 2	Area 3	Other

Research acoustic survey length frequencies by area

The 1997, 2002, 2006 and 2011 acoustic survey abundance at length data were converted to a length frequency using the combined sexes fixed length-weight relationship (“unsexed” in table 1, Biology section above) to convert the abundance to numbers at length (Table 3).

Absolute abundance estimates from the 1997, 2002, 2006 and 2011 acoustic surveys

Absolute estimates of abundance for black oreo are available from four acoustic surveys of oreos carried out from 10 November to 19 December 1997 (TAN9713), 25 September to 7 October 2002 (TAN0213), 17–30 October 2006 (TAN0615) and 17 November to 1 December 2011 (SWA1102). The 1997 survey covered the “flat” with a series of random north-south transects over six strata at depths of 600–1200 m. Seamounts were also sampled using parallel and “starburst” transects. Targeted and some random (background) trawling was carried out to identify targets and to determine species composition. The 2002 survey was limited to flat ground with 77 acoustic transect and 21 mark identification tows completed. The 2006 (78 transects and 22 tows) and 2011 (72 transects and 25 tows) surveys were very similar to the 2002 survey and covered the main area of the black oreo fishery. The estimated total abundance (immature plus mature) for each survey by area is shown in Table 4.

Table 3: Research length frequency proportions for the model area for the 1997, 2002, 2006 and 2011 acoustic surveys.
 - no data for 1997 to 2006, lengths below 25 cm and greater than 38 were pooled.

Table 4: Total (immature plus mature) black oreo abundance estimates (t) and CVs for the 1997, 2002, 2006 and 2011 acoustic surveys for the three model areas in OEO 3A.

Acoustic survey	Area 1	Area 2	Area 3	Total
1997	148 000 (29)	10 000 (26)	5 240 (25)	163 000 (26)
2002	43 300 (31)	15 400 (27)	4 710 (38)	64 000 (22)
2006	56 400 (37)	16 400 (30)	5 880 (34)	78 700 (30)
2011	138 100 (27)	36 800 (30)	7 400 (34)	182 300 (25)

Relative abundance estimates from standardised CPUE analysis

Standardised CPUE indices were obtained for each area. Because of the apparent changes in fishing practice attributable to the introduction of GPS, the data were split into pre- and post-GPS series. There were also major changes in the fishery from 1998–99 to 2001–02 when there were TACC reductions and the start of a voluntary industry catch limit on smooth oreo (1998–99). Two post-GPS series were therefore developed. The first of these was from 1992–93 to 1997–98 (early series) and the second was from 2002–03 onwards (late series) with data from the intervening years ignored. Since there are no new data for either the pre-GPS series or the post-GPS early series, these are left unchanged from previous standardisation results. Only the post-GPS late series is updated here, using data that extends from 2002–03 to 2011–12.

Only data within a pre-defined spatial area were considered useful for assessing abundance (Figure 2).

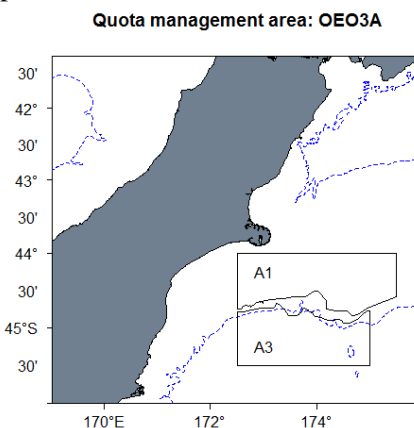

Figure 2: Spatial areas from which CPUE data were collected for inclusion in the standardisation. Areas A1 and A3 are shown, with A2 being the area between the two.

OREOS (OEO 3A)

This area corresponds to the main fishing area and overlaps with the acoustic survey area (Figure 1). Tows were initially selected for inclusion in the CPUE standardisation if they targeted or caught black oreo within this area.

Uncertainty was assessed by bootstrapping the data, re-estimating the indices for each iteration, and estimating the coefficient of variation (CV) for each year/area from this distribution. The indices and CV estimates are listed in Table 5 and shown in Figure 3.

Table 5: OEO 3A black oreo pre-GPS and post-GPS time series of standardised catch per unit effort indices and bootstrapped CV estimates (%). Values for each series have been renormalized to a geometric mean of one. -, no estimate.

Figure 3: Standardised commercial CPUE series for black oreo in each area within OEO 3A. Pre-GPS and post-GPS (early and late) series are shown, each renormalized to a geometric mean of one. Error bars represent the 95% confidence intervals assuming a log-normal error distribution and using the CVs listed in Table 5.

4.3 Smooth oreo

2009 assessment

The stock assessment analyses were conducted using the CASAL age-structured population model employing Bayesian statistical techniques. The 2005 assessment was updated by including five more years of catch, CPUE and observer length data, and used two new series of post-GPS standardised CPUE, one before and the second after major TACC and catch limit changes. The modelling took account of the sex and maturity status of the fish and treated OEO 3A as a single smooth oreo fishery, i.e., no sub-areas were recognised. The base case model used the 1997 absolute acoustic abundance estimate, pre-GPS and early and late post-GPS series of standardised CPUE indices, and the mean natural mortality estimate (0.063 yr^{-1}). Acoustic and observer length frequencies were used in a preliminary model run to estimate selectivity and the base case fixed these selectivity estimates but did not use the length frequencies. Other cases investigated the sensitivity of the model to data sources including:

- Use of the upper and lower 95% confidence interval values for estimates of natural mortality ($0.042\text{--}0.099 \text{ yr}^{-1}$);
- Use of only the left hand limb of the 1994 observer length frequency (plus the 1997 acoustic survey length frequency) with growth not estimated by the model.

4.3.1 Estimates of fishery parameters and abundance

Catch history

The estimated catches were scaled up to the total reported catch (see tables 2 and 3 in the Fishery Summary section at the beginning of the Oreos report) and are given in Table 6.

Table 6: Reconstructed catch history (t)

† Soviet catch, assumed to be mostly from OEO 3A and to be 50:50 black oreo:smooth oreo.

Observer length frequencies

Observer length data were extracted from the observer database. These data represent proportional catch at length and sex. All length samples were from the CPUE study area (see Figure 4). Only samples where 30 or more fish were measured, and the catch weight and a valid depth were recorded, were included in the analysis. Data from adjacent years were pooled because of the paucity of data in some years. The pooled length frequencies were applied in the model at the year that the median observation of the grouped samples was taken (Table 7).

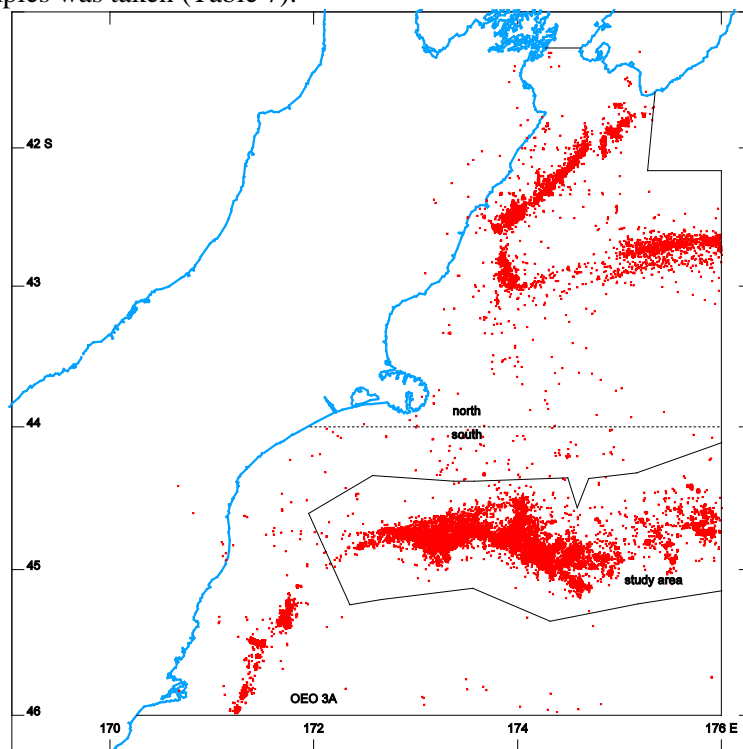

Figure 4: Locations of all tows in OEO 3A with a reported catch of smooth oreo from 1979–80 to 2002–03 (dots). The study area is shown along with the line chosen to split north from south Chatham rise catches.

Length frequency data from the 1997 acoustic survey

Length data collected during the 1997 survey were used to generate a population length frequency by sex. A length frequency was generated from the trawls in each mark-type and also for the seamounts. These frequencies were combined using the fraction of smooth oreo abundance in each mark-type. The overall frequency was normalised over both male and female frequencies so that the sum of the frequencies over both sexes was 100%. The CV for each length class was given by the regression, $\log(\text{CV}) = 0.86 + 8.75/\log(\text{proportion})$. This regression was estimated from the CVs obtained by bootstrapping the data and provides a smoothed estimate of the CVs. The estimated length frequency is in Figure 5.

Absolute abundance estimates from the 1997 acoustic survey

Absolute estimates of abundance for smooth oreo are available from the acoustic survey on oreos carried out from 10 November to 19 December 1997 (TAN9713) using the same approach as described for OEO 3A black oreo. The abundance estimates used in the 1999 OEO 3A smooth oreo assessment were revised in 2005 using new target strength estimates for smooth oreo, black oreo and a number of bycatch species. The revised estimate was 25 200 t with a CV of 23% (the 1999 estimate was 35 100 t with a CV of 27%). There is uncertainty in the estimates of biomass because the acoustic estimate includes smooth oreo in layers that are a mixture of species for which the acoustic method has potential bias problems.

Figure 5: Population length frequency derived from the 1997 acoustic survey data. The bold line is the estimated value and the shaded area is the spread from 300 bootstraps.

Relative abundance estimates from standardised CPUE analysis

The CPUE study area is shown in Figure 4. Three analyses were carried out; a pre-GPS analysis (unchanged from 2005) that included data from 1980–81 to 1988–89 and two post-GPS analyses that included data from 1992–93 to 1997–98 and 2002–03 to 2007–08. The years from 1998–99 to 2001–02 were not included because a voluntary smooth oreo catch limit (1400 t) was introduced and substantial oreo TACC reductions were made during that time (6600 down to 3100 t). The pre-GPS series shows a downward trend, and declines to approximately a third of the initial level over the nine-year period. The early post-GPS also has a downward trend but the late post-GPS series has an upward trend and then flattens out. The base case stock assessment used all three indices (Table 8).

Fishing Industry members of the Deepwater Fishery Assessment Working Group expressed concern about the accuracy of the historical Soviet catch and effort data (pre-GPS series) and felt that it was inappropriate to use those data in the stock assessment.

Table 8: CPUE indices by year and jackknife CV (%) estimates from the pre-GPS and the two post-GPS analyses.

Year	Pre-GPS			Year	Index	CV	Post-GPS		
	Index	CV					Year	Index	CV
1980–81	1.00	27	1992–93	1.00	24		2002–03	0.55	23
1981–82	0.82	26	1993–94	0.88	11		2003–04	0.77	22
1982–83	0.72	62	1994–95	0.74	14		2004–05	0.99	22
1983–84	0.59	61	1995–96	0.48	17		2005–06	0.96	31

1985–86	0.61	19	1997–98	0.50	19		2007–08	0.92	21
1986–87	0.46	16							
1987–88	0.42	16							
1988–89	0.26	28							

4.3.2 Biomass estimates

The posterior distributions from the MCMC on the base case are shown in Figure 6. The probability that the current mature biomass (2008–09) and the biomass 5 years out (2013–14) are above 20% B_0 is 1 for both.

Biomass estimates derived from the MCMC are in Table 9. Total mature biomass for 2008–09 was estimated to be 36% of the initial biomass (B_0). Sensitivity case results for the base case using the lower and upper 95% confidence interval value estimates for M gave estimates of current biomass between 26% and 49% of B_0 . The sensitivity case that used the left hand limb of the 1994 observer length frequency (plus the 1997 acoustic survey length frequency) with growth not estimated by the model gave estimates of current biomass for the mean estimate of M (0.063 yr^{-1}) of 30 % of B_0 while estimates using the lower and upper 95% confidence interval value estimates for M gave estimates of 2008 biomass between 12% and 59% of B_0 .

Projections were carried out for five years with the current catch limit of 1400 t. The trajectory shows increasing biomass (Figure 6).

4.3.3 Other factors

Because of differences in biological parameters between the species, it would be appropriate to split the current TACC for black oreo and smooth oreo. The WG noted that separate species catch limits are in place to reduce the risk of over- or under-fishing either smooth oreo or black oreo.

The model estimates of uncertainty are unrealistically low. Uncertainties that are not included in the model include:

- the assumption that recruitment is deterministic;
- that the acoustic index is assumed to be an absolute estimate of abundance;
- the selectivity in the base case is fixed at the MPD estimate from the preliminary case where all length data is used;
- uncertainty in the estimate of M .

In addition, the growth is fixed and known. The WG has previously noted the impact of the different ages of maturity for males and females. Due to the fact that males mature at a much smaller size than

females (age at 50% maturity is 18–19 years for males and 25–26 for females), the sex ratio needs to be taken into account when assessing the sustainability of any particular catch level.

Figure 6: Smooth oreo OEO 3A: posterior distribution for the virgin biomass (top plot) and the mature biomass trajectories as a percentage of virgin biomass (bottom plot) from the MCMC analysis of the “NoLF” case with $M = 0.063$ (base case). In the top plot, the vertical line is the median of the distribution. In the bottom plot, the grey area is the point-wise 95% confidence intervals of the trajectories and the solid line is the median.

Table 9 (a): Base case (in bold) and sensitivity to M values (biomass estimates). Bcurr is 2008.

	$M = 0.063$			$\dagger M = 0.042$			$\dagger M = 0.099$

$B_{cur}(\%B_0)$	30	27	33	12	10	14	59	56	63

5. STATUS OF THE STOCKS

The smooth oreo stock assessment is unchanged from 2009. The black oreo stock assessment is updated using CPUE data up to 2011–12.

Stock Structure Assumptions

The two oreo stocks in FMA 3A are assessed separately but managed as a single stock. For both the black oreo and smooth oreo stocks it is assumed that there is potential mixing with stocks outside of the OEO 3A area.

Qualifying Comments
-

Fishery Interactions

Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries, mostly in other areas e.g. OEO 4. The main bycatch species in the OEO 3A black oreo target fishery include smooth oreo, hoki, javelinfish, Baxter's dogfish, pale ghost shark, ridge scaled rattail, and basketwork eel. Bycatch species that may be vulnerable to overfishing include deepwater sharks and rays. Protected species catches include seabirds and deepwater corals.

Fishery Interactions
Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries, mostly in other areas e.g. OEO 4. The main bycatch species in the OEO 3A smooth oreo target fishery include black oreo, hoki, javelinfish, Baxter's dogfish, pale ghost shark, ridge scaled rattail and basketwork eel. Low productivity bycatch species include deepwater sharks and rays. Protected species catches include seabirds and deepwater corals.

OREOS – OEO 4 BLACK OREO AND SMOOTH OREO

1. FISHERY SUMMARY

This is presented in the Fishery Summary section at the beginning of the Oreo report.

2. BIOLOGY

This is presented in the Biology section at the beginning of the Oreo report.

3. STOCKS AND AREAS

This is presented in the Stocks and Areas section at the beginning of the Oreo report.

4. STOCK ASSESMENT

4.1 Introduction

In 2018, the stock assessment was updated for smooth oreo in OEO 4.

4.2 Black oreo

Investigations were carried out in 2009 using age-based single sex single step preliminary models in CASAL. The data used in these models were four standardised CPUE indices (pre- and post-GPS in the east and west), and observer length frequencies. Growth and maturity were also estimated in some of the runs.

4.2.1 Estimates of fishery parameters and abundance

Absolute abundance estimates from the 1998 acoustic survey

Absolute estimates of abundance were available from an acoustic survey on oreos which was carried out from 26 September to 30 October 1998 on *Tangaroa* (voyage TAN9812). Transects on flat ground were surveyed to a stratified random design and a random sample of seamounts were surveyed with either a random transect (large seamounts) or a systematic “star” transect design. For some seamounts the flat ground nearby was also surveyed to compare the abundance of fish on and near the seamount either by extending the length of the star transects or by extra parallel transects. Acoustic data were collected concurrently for flat and seamounts using both towed and hull mounted transducers. The OEO 4 survey covered 59 transects on the flat and 29 on seamounts. A total of 95 tows were carried out for target identification and to estimate target strength and species composition. In situ and swimbladder samples for target strength data were collected and these have yielded revised estimates of target strength for both black oreo and smooth oreo.

Acoustic abundance estimates for recruit black oreo from seamounts and flat for the whole of OEO 4 are in Table 1. About 59% of the black oreo abundance came from the background mark-type. This mark-type is not normally fished by the commercial fleet and this implies that the abundance estimate did not cover the fish normally taken by the fishery. In addition the scaling factor to convert the acoustic area estimate to the trawl survey area estimate was 4.3, i.e., the acoustic survey area only had about 23% of the abundance. The magnitude of this ratio suggests that the size of the area surveyed was borderline for providing a reliable abundance estimate.

Table 1: OEO 4 recruit black oreo seamount, flat, and total acoustic abundance estimates (t) and recruit CV (%) based on knife-edge recruitment (23 years).

	Abundance (t)	CV (%)
Seamount	127	91
Flat	13 800	56
Total	13 900	55

Relative abundance estimates from standardised CPUE analyses – 2009 analysis

The CPUE analysis method involved regression based methods on the positive catches only. Sensitivities were run where the positive catch tow data and the zero catch tow data were analysed separately to produce positive catch and zero catch indices. All data were included, whether they were target or bycatch fisheries, with the target offered to the model (and not accepted).

The best data-split was investigated using the Akaike Information Criteria (AIC) on a number of potential regressions. Four indices were subsequently used, pre- and post-GPS in the east and west areas respectively. These two areas are very distinct: the west consists of flat fishing and the east of hill fishing, the west area was fished 10 years prior to the east, and there has been a move by the fishery since the early 1990s from the west to the east. However, despite these differences, the two series present almost identical patterns of decline in relative standardised CPUEs from the time fishing started in earnest (1980 in the west and 1992 in the east) which would suggest that for this fishery CPUE might be a reasonable index of abundance (because less influenced by technology, fishing patterns, hills or flats etc).

The standardised CPUE series and CVs are described in Table 2. Over comparable time periods and data sets, the trends from the updated series were similar to those from the 2000 analyses (Coburn et al 2001b). The west CPUE reduced to between 5% of the 1980 value and 15% of the 1981 value by 1990. The post-GPS west series is either flat or slightly increasing. The east CPUE reduced to 4% of the 1984 value and 21% of the 1985 value by 1990 even though catches were low. The post-GPS east series showed a further steep initial decline with total reduction to 15% of the 1993 value by 2008.

Table 2: OEO 4 black oreo standardised CPUE analyses in 2009 (expressed in t / tow).

Fishing year	Pre-GPS east		Pre-GPS west		Fishing year	Post-GPS east		Post-GPS west	
	Index	CV	Index	CV		Index	CV	Index	CV
1980			8.97	0.17	1993	0.71	0.15	0.73	0.41

					2007	0.12	0.07	1.00	0.27
					2008	0.10	0.09	0.88	0.24

Relative abundance estimates from trawl surveys

The estimates, and their CVs, from the four standard *Tangaroa* south Chatham Rise trawl surveys are treated as relative abundance indices (Table 3).

Table 3: OEO 4 black oreo research survey abundance estimates (t). N is the number of stations. Estimates were made using knife-edge recruitment set at 33 cm TL. Previously knife-edge recruitment was set at 27 cm and estimates of abundance based on that value are also provided for comparison.

Year	Mean abundance		CV (%)	N
	27 cm	33 cm		
1991	34 407	13 065	40	105
1992	29 948	12 839	46	122
1993	20 953	6 515	30	124
1995	29 305	9 238	30	153

Observer length frequencies

Observer length frequencies were available for about 20% of the yearly catch from 1989 to 2008. Analyses conducted on these data indicated that they were not representative of the spatial spread of the fishery. When stratified by depth, the length frequencies had double-modes, centred around 28 cm and 38 cm, with inconsistent trends in the modes between years. Alternative stratification by subarea, hill, etc, did not resolve the problem; some tows showed bimodality. These patterns in length frequencies were an issue because the yearly shifts in length frequencies and double mode cannot be representative of the underlying fish population since black oreo is a slow growing long-lived fish. They are more likely linked with discrete spatial sub-groups of the population.

A similar double mode was reported for some strata in the same area from the 1994 *Tangaroa* trawl survey (Tracey & Fenaughty 1997). It is likely that there is further spatial stock structure that is currently unaccounted for.

4.2.2 Biomass estimates

The 2009 stock assessment of OEO 4 black oreo was inconclusive as assessment models were unable to represent the observer length frequency structure, and were considered unreliable. The CPUE was fitted satisfactorily under a two-stock model but could not be fitted in a single homogeneous stock model. However, the WG agreed that:

1. The CPUE indices are consistent with a two-stock structure or at least a minimally-mixing single stock.
2. The updated CPUE estimates were probably a reasonable indicator of abundance (at the spatial scale of the east and west analyses).

4.2.3 Estimation of Maximum Constant Yield (MCY)

In 2000, MCY was estimated using the equation, $MCY = c * Y_{AV}$ (Method 4). There was no trend in the annual catches, nominal CPUE, or effort from 1982–83 to 1987–88 so that period was used to calculate the MCY estimate (1200 t). The MCY calculation was not updated in 2009.

4.2.4 Estimation of Current Annual Yield (CAY)

CAY cannot be estimated because of the lack of current biomass estimates.

4.3 Smooth oreo

Smooth oreo was assessed in 2018 using a CASAL age-structured population model with Bayesian estimation, incorporating stochastic recruitment, life history parameters (table 1 of the Biology section at the beginning of the Oreo report), and catch history up to 2017–18. In early assessments (Doonan et al 2001, 2003, 2008), the stock area was split at 178° 20' W into a west and an east fishery based on an analysis of commercial catch, standardised CPUE, and research trawl and acoustic result, and data fitted in the model included acoustic survey abundance estimates, standardised CPUE indices, observer length data, and the acoustic survey length data. In 2012, the Deepwater Working Group decided that using CPUE to index abundance should be discontinued, due to changes in fishing patterns over time within the stock area. With no CPUE indices, the 2012 assessment was simplified to a single area model using only the observations of vulnerable biomass from acoustic surveys carried out in 1998, 2001, 2005, and 2009.

A 2014 stock assessment updated the 2012 assessment model using the same single area model structure and used an additional observation of biomass from the research acoustic survey carried out in 2012. The assessment also revised the previous assessments by including the age frequency estimates from

the 1998 and 2005 acoustic surveys and by estimating relative year class strengths. The 2018 assessment updated the 2014 assessment with the inclusion of an additional acoustic survey biomass estimate in 2016 and the associated age frequency. An age frequency from a 1991 trawl survey was also included together with an age frequency from the commercial fishery in 2009. With the addition of three new age frequencies natural mortality was estimated within the model (with a Normal prior with the mean equal to 0.063 and CV=25% – see table 1 in the Biology section).

Year class strengths (YCS) were estimated for 1940–2005 (based on the range of age estimates in the age frequency data). A “near uniform” prior was used (parameterised as a lognormal distribution with a mode of 1 and sigma of 4), which places minimum constraint on the free YCS parameters (Haist parameterisation).

An informed prior was used for the acoustic survey proportionality constant q (lognormal with mean of 0.83 and CV of 0.3). The prior was based on limited information on target strength, the QMA scaling-factor, and the proportion of vulnerable biomass in the vulnerable acoustic marks (Fu & Doonan 2013).

A brief description of the base case and sensitivity runs presented are summarised in Table 4. The following assumptions were made in the stock assessment analyses:

- (a) Recruitment followed a Beverton–Holt relationship with steepness of 0.75.
- (b) Catch overruns were 0% during the period of reported catch.
- (c) The population of smooth oreo in OEO 4 was a discrete stock or production unit.
- (d) The acoustic biomass selectivity and the commercial fishery selectivity were assumed to be identical (logistic, estimated within the model).
- (e) A separate selectivity was estimated for the age frequencies that were derived from trawl catches during the acoustic surveys (double normal, estimated within the model).

Bayesian estimation was used in the assessment to capture the uncertainties in model estimates of biomass and other parameters:

1. Model parameters were estimated using maximum likelihood and the prior probabilities;
2. Samples from the joint posterior distribution of parameters were generated with the Monte Carlo Markov Chain procedure (MCMC) using the Hastings-Metropolis algorithm;
3. A marginal posterior distribution was found for each quantity of interest by integrating the product of the likelihood and the priors over all model parameters; each marginal posterior distribution was described by its median and a 95% credibility interval (95% CI).

Bayesian estimates were based on results from three 15 million long MCMC chains. After a burn-in of 1 million, the last 14 million of the chain was sampled at each 1000th value. Posterior distributions were obtained from samples combined over the three chains (after the burn-in).

Table 4: Descriptions of the model runs of the 2018 smooth oreo assessment. LN, lognormal distribution with mean and CV given in the bracket. N, normal distribution with mean and CV in the bracket. All use Haist parameterisation for YCS.

Model run	Description
Base	Acoustic q estimated with a LN(0.83, 0.3) prior, nearly uniform prior on YCS, M estimated with a N(0.063, 0.25) prior, adult biomass indices (school marks)
LowM-High q	M fixed at 0.0632 (20% less than the base estimate) and the mean of the acoustic q prior 20% higher
HighM-Low q	M fixed at 0.0948 (20% higher than the base estimate) and the mean of the acoustic q prior 20% lower
Plus LFs	Base but with commercial length frequencies included
Fixed M	Base but with fixed $M = 0.063$ (as assumed in the 2014 assessment)

4.3.1 Estimates of fishery parameters and abundance

The 2018 assessment incorporated the catch history and the adult acoustic biomass indices. Five age frequencies were fitted. Commercial length frequencies (five scaled length frequencies between 1996 and 2008) were not included in the base model but were fitted in a sensitivity run (see Table 4).

Catch history

A catch history for smooth oreo in OEO 4 was developed by scaling the estimated catch to the QMS values (Table 5). A catch of 2500 t was assumed for 2017–18.

Table 5: Catch history for OEO 4 smooth oreo

Year	Catch (t)	Year	Catch (t)
1978–79	1 321	1999–00	6 357
1979–80	112	2000–01	6 491
1980–81	1 435	2001–02	4 291

1992–93	5 911	2013–14	6 016
1993–94	6 283	2014–15	6 318
1994–95	6 936	2015–16	1 992
1995–96	6 378	2016–17	2 279
1996–97	6 359	2017–18	2 500
1997–98	6 248		
1998–99	6 030		

Biomass estimates from the 1998, 2001, 2005, 2009, 2012, and 2016 acoustic surveys

Estimates of biomass were available from six acoustic surveys:

- (i) 26 September to 30 October 1998 on *Tangaroa* (voyage TAN9812);
- (ii) 16 October to 14 November 2001 using *Tangaroa* for acoustic work (voyage TAN0117) and *Amaltal Explorer* (voyage AEX0101) for trawling;
- (iii) 3–22 November 2005 using *Tangaroa* for acoustic work (voyage TAN0514) and 3–20 November 2005 using *San Waitaki* (SWA0501) for mark identification trawling;
- (iv) 2–18 November 2009 using *Tangaroa* for acoustic work (voyage TAN0910) and 2–18 November 2009 using *San Waitaki* (SWA0901) for mark identification trawling;
- (v) 8–26 November 2012 using *Tangaroa* for acoustic work (voyage TAN01214) and 8–26 November 2012 using *San Waitaki* (SWA1201) for mark identification trawling;
- (vi) 16 October to 17 November 2016 on *Amaltal Explorer* (AEX1602).

The method of estimating variance and bias was the same as in previous oreo surveys (Doonan et al 1998, 2000). Variance was estimated separately for the flat and for hills and then combined. Sources of variance were:

- sampling error in the mean backscatter
- the proportion of smooth oreo and black oreo in the acoustic survey area
- sampling error in catches which affects the estimate of the proportion of smooth oreo
- error in the target strengths of other species in the mix
- variance in the estimate of smooth oreo target strength
- sampling error of fish lengths (negligible)
- variance of the mean weight, for smooth oreo

Vulnerable smooth oreo was estimated based on the acoustic mark types, where vulnerable biomass was the sum over two flat mark types: DEEP SCHOOLS and SHALLOW SCHOOLS, with the hill biomass added on. These estimates were made for smooth oreo in the whole of OEO 4 (Table 6).

One major source of uncertainty in the 2012 survey estimates was that about 25% of the total estimate came from one school mark on the flat. The species composition of this mark was not able to be verified by trawling. Excluding this mark, i.e., assuming they were not smooth oreo, reduced the total biomass for smooth oreos to 36 550 t. However, the consensus of skippers consulted about the mark is that it was likely to be smooth oreo.

Table 6: Estimated smooth oreo vulnerable biomass (t) and CV (%), after the addition of 20% process error) from acoustic surveys in 1998, 2001, 2005, and 2009, 2012, and 2016; includes school marks and hills.

Year	Biomass (t)	CV (%)
1998	65 679	33
2001	81 633	33
2005	63 237	32
2009	26 953	33
2012	58 603	36
2016	34 022	38

Age frequencies from the 1998, 2005, and 2016 acoustic surveys

Age frequency distributions were derived from trawl samples taken for smooth oreo in OEO 4 during three acoustic surveys carried out in 1998 and 2005 (Doonan et al 2008) and 2016. All of the sampled otoliths ($n = 546$) from the 1998 survey and randomly selected otoliths ($n = 500$) from the 1800 otoliths collected during the 2005 survey were read, with 398 otoliths used from the 2016 survey.

The age frequency distribution was estimated using the aged otoliths from tows in each mark-type weighted by the catch rates and the proportion of abundance in the mark-type. Age frequencies were estimated by sex and combined over sexes. The variance was estimated by bootstrapping the tows within mark-types (e.g., Doonan et al 2008). The ageing error was estimated by comparing age estimates from two readers and also by using repeated readings from the same reader. The age frequencies had a mean weighted CV of 36% (1998) and 45% (2005). The ageing error was estimated to be about 8.5% which was used in the assessment. The age frequencies (male and female combined) were included in order to estimate year class strength.

Other age frequencies

Two additional age frequencies were constructed for the 2018 assessment. The first was for the commercial catch in 2008–2009. The 1284 otoliths available from the observer programme were sampled at random (with replacement) until 400 unique otoliths were obtained. The probability of selection was proportional to the tow catch and inversely proportional to the number of otoliths sampled in the tow. The mean weighted CV was 30% (obtained by bootstrapping). The second age frequency was constructed for the 1991 trawl survey of OEO 4 (TAN9104). Otoliths collected during the trawl survey were sampled at random until 400 unique otoliths were obtained. The probability of selection was proportional to the stratum biomass estimate and by tow catch within stratum, divided by the number of otoliths available from the tow. The mean weighted CV was 35% (obtained by bootstrapping).

Observer length frequencies

Observer length data were extracted from the observer database. These data were stratified by season (October–March and April–September) and into west and east parts. The length frequencies were combined over strata by the proportion of catch in each stratum.

Five scaled length frequencies from 1996 to 2008 were used in a sensitivity run but not used in the base model.

4.3.2 Biomass estimates, year class strengths, and exploitation rates

For the base model, and all of the sensitivities, B_0 was estimated at about 140 000 t with 95% CIs ranging from about 110 000 t to 210 000 t (Table 7). Current stock status is estimated to be at the target level of 40% for the base case. However, it is estimated to be just above 30% B_0 for the LowM-Highq and Fixed M runs (Table 7). For all of the runs the estimated probability of current stock status being below the soft limit of 20% B_0 is less than 5% (Table 7). The probability of current stock status being below the hard limit of 10% B_0 was estimated at 0 for all runs (Table 7).

Table 7: Bayesian estimates of M , B_0 , and current stock status (B_{18}/B_0) for the base model and sensitivities (the median and 95% CIs are given). The probability of current stock status being below 10% or 20% B_0 is also given.

	M (yr ⁻¹)	B_0 (000 t)	ss_{18} (% B_0)	$P(ss_{18} < 10\%)$	$P(ss_{18} < 20\%)$
Base	0.079 (0.057–0.01)	138 (111–184)	40 ((23–59)	0.00	0.01
LowM-Highq	0.0632	138 (118–173)	31 (19–46)	0.00	0.04
HighM-Lowq	0.0948	146 (111–208)	50 (33–67)	0.00	0.00
Incl. LFs	0.085 (0.067–0.011)	133 (111–172)	42 (26–60)	0.00	0.00
Fixed M	0.063	143 (121–184)	33 (21–50)	0.00	0.02

The spawning biomass trajectory for the base model shows a decreasing trend from the start of the fishery in the 1980s with a flattening off in 2015–16 when catches were substantially reduced (Figure 1, Table 5). Current stock status is estimated to be at the target biomass although the 95% CIs are very wide (Figure 1, Table 7).

The estimated year class strengths show a pattern (in the medians) from 1972 to 1987 of above average cohort strength with below average cohort strength from 1990 to 2005 (Figure 2), consistent with the age composition data.

Figure 1: Base, MCMC estimated spawning-stock biomass trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The soft limit (red) and target biomass (green) are marked by horizontal lines.

Figure 2: Base, MCMC estimated “true” YCS (R_y/R_0). The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution.

Exploitation rates in the fishery were estimated to be generally increasing from the start of the fishery up until 2014–15 (Figure 3). Catches in the years immediately prior to the TACC reduction in 2015–16 were at a level increasingly above the exploitation rate corresponding to the target biomass, $U_{40\%B_0}$. With the substantial catch reduction in 2015–16 the estimated exploitation rate (median) dropped to below 5% where it has remained (Figure 3).

Figure 3: Base, MCMC estimated exploitation rate trajectory. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The exploitation rate, $U_{40\%B_0}$, corresponding to the biomass target of 40% B_0 is marked by the middle horizontal line ($U_{x\%B_0}$ is the exploitation rate that will drive deterministic spawning biomass to $x\% B_0$). $U_{30\%B_0}$ and $U_{50\%B_0}$ are also marked by horizontal lines.

4.3.3 Yield estimates and projections

Five year projections were made from the base model at a constant catch of 2300 t which is the approximate level of the last reported annual catch (2279 t in 2016–17) and also at 3000 t (the TACC for OEO 4). Year class strengths from 2006 onwards were sampled at random from the last 10 estimated year class strengths (1996–2005). Based on the projections, stock status is expected to stay fairly constant over the next five years for annual catches in the range 2300–3000 t (Figures 4 and 5, Table 8). There is a small upward trend in median stock status at annual catches of 2300 t (Figure 4, Table 8).

Figure 4: Base, MCMC projections at a constant annual catch of 2300 t. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The target biomass (40% B_0) is marked by the horizontal green line and the soft limit (20% B_0) by the horizontal red line.

Figure 5: Base, MCMC projections at a constant annual catch of 3000 t. The box in each year covers 50% of the distribution and the whiskers extend to 95% of the distribution. The target biomass (40% B_0) is marked by the horizontal green line and the soft limit (20% B_0) by the horizontal red line.

Table 8: The expected value of stock status in 2023 ($E(ss_{23})$) and the probabilities of being above the target biomass (40% B_0) or below the soft limit (20% B_0) or below the hard limit (10% B_0) under projected annual catches of 2300 t or 3000 t.

Annual catch (t)	$E(ss_{23})$ (% B_0)	$P(ss_{23} > 40\%)$	$P(ss_{23} < 20\%)$	$P(ss_{23} < 10\%)$
2300	42	0.57	0.01	0.00
3000	40	0.49	0.02	0.00

4.3.4 Other factors

The Working Group considered that there were a number of other factors that should be considered in relation to the stock assessment results presented here. These include:

- uncertainty in the estimates of species composition of catch histories,
- confounding of estimates of M with others parameters in the model, and
- the assumption that acoustic selectivity is the same as the commercial selectivity.

4.3.5 Future research considerations

- Regular acoustic surveys are required to monitor the trend in adult biomass.
- Improved estimates of smooth oreo target strength would reduce the uncertainty in the assessment as would additional age frequency data.
- A continued emphasis on mark identification of large schools during the surveys is important.
- Sensitivities to assumptions about the species composition in deriving catch histories could be insightful.
- It would also be useful to investigate correlations between model parameters.
- A more generic research consideration, possibly to be undertaken by the Stock Assessment Methods Working Group, is to develop guidelines for when M should be estimated in models, and when (and how) it should be independently estimated.

5. STATUS OF THE STOCKS

There is an updated stock assessment in 2018 for the smooth oreo stock in OEO 4.

Stock Structure Assumptions

Black and smooth oreo in OEO 4 are assessed separately but managed as a single stock (although catches are often estimated separately). For black oreos the population has been found to be genetically similar to other oreo stocks and it is likely that some mixing occurs. Smooth oreos in OEO 4 are assumed to be distinct from OEO 1 and 6 stocks but may mix with the 3A stock.

- **OEO 4 (Black Oreos)**

Stock Status	
Year of Most Recent Assessment	2009
Assessment Runs Presented	No quantitative stock assessment model
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: Not defined
Status in relation to Target	Unknown
Status in relation to Limits	Unknown
Status in relation to Overfishing	-

Historical Stock Status Trajectory and Current Status
<No plot available>

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	CPUE has been stable for the last 5 years, after initial substantial decline during the 1980s and 1990s.
Recent Trend in Fishing Mortality or Proxy	Unknown
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Unknown
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unknown

Assessment Methodology and Evaluation		
Assessment Type	Level 2 – Partial Quantitative Stock Assessment	
Assessment Method	Age-based model in CASAL	
Period of Assessment	Latest assessment: 2009	Next assessment: Unknown
Overall assessment quality rank	-	
Main data inputs (rank)	- 4 standardised CPUE indices (pre/post GPS and east/west) - Observer length frequencies	- -
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	None	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Assessments unable to represent observer length frequency data. - CPUE could be fitted to a two-stock model but not a homogenous model. - A portion of the abundance estimates were based on data from areas not normally covered by the trawl fishery, and the surveyed area was scaled by a factor of 4.3 – the area surveyed was borderline for providing a reliable abundance estimate. 	

Qualifying Comments
The Working Group agreed that the stock might be split into east and west areas that were independent or at least minimally mixing for future assessments.

Fishery Interactions
Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries and in smaller numbers in hoki target fisheries. Target fisheries for oreos do exist, with main bycatch being orange roughy, rattails and deepwater sharks. Bycatch species recorded include deepwater sharks and rays, seabirds and deepwater corals.

- **OEO 4 (Smooth Oreos)**

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	Base model fitted to vulnerable acoustic biomass estimates, based on school marks, and age frequencies
Reference Points	Target: 40% B_0 Soft limit: 20% B_0 Hard limit: 10% B_0 Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	B_{2018} was estimated at 40% B_0 for the base model. B_{2018} is About as Likely as Not (40-60%) to be at or above the target.
Status in relation to Limits	B_{2018} is Very Unlikely (< 10%) to be below the Soft limit and Exceptionally Unlikely (< 1%) to be below the Hard Limit.
Status in relation to Overfishing	Overfishing is Unlikely (< 40%) to be occurring.

Historical Stock Status and Exploitation Rate Trajectory

Historical trajectory of spawning biomass (% B_0) and exploitation rate (%) (base model, medians of the marginal posteriors). A reference range of 30-50% B_0 and the corresponding exploitation rate range are coloured in green. The soft limit (20% B_0) is marked by a red line and the target biomass (40% B_0) and corresponding exploitation rate are marked by blue lines.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	There has been little change in estimated biomass in the last 4 years.
Recent Trend in Fishing Intensity or Proxy	Following the large reduction in TACC and catch in 2015–16, estimated exploitation rates declined.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	Below average cohort strength was estimated from 1990 to 2005.

Projections and Prognosis	
Stock Projections or Prognosis	Little change in projected biomass over the next five years at annual catches of 2300–3000 t
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Very Unlikely (< 10%) Hard Limit: Exceptionally Unlikely (< 1%)
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unlikely (< 40%) for the current catch or TACC

Assessment Methodology and Evaluation		
Assessment Type	Type 1 – Full Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions	
Assessment Dates	Latest assessment : 2018	Next assessment: 2022
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Six acoustic biomass indices (1998, 2001, 2005, 2009, 2012, 2016) - Age frequencies from acoustic surveys (1998, 2005, 2016) - Trawl survey age frequency (1991) - Commercial age frequency (2009) - Observer length data (used in a sensitivity) 	<ul style="list-style-type: none"> 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality 1 – High Quality
Data not used (rank)	- Commercial CPUE	3 – Low Quality: substantial changes in fishing patterns over time
Changes to Model Structure and Assumptions	- Added age data (trawl survey and commercial) and estimated M in the model	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Uncertainties in the prior for the survey catchability (q) <ul style="list-style-type: none"> o estimated target strength o scaling factor from the trawl survey area to acoustic area o scaling factor from acoustic area to the QMA area o proportion of vulnerable biomass in the surveyed marks o acoustic mark identification - Single commercial age frequency - Confounding of estimates of M with other parameters in the model - Assumption that acoustic selectivity is the same as the commercial selectivity 	

Qualifying Comments
-

Fishery Interactions
Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries and in smaller numbers in hoki target fisheries. Target fisheries for oreos do exist, with main bycatch being orange roughy, rattails and deepwater sharks. Low productivity species taken in oreo fisheries include orange roughy, rattails, and deepwater sharks and rays. Incidental captures have also been recorded for seabirds and deepwater corals.

OREOS - OEO 1 AND OEO 6 BLACK ORO AND SMOOTH ORO

1. FISHERY SUMMARY

This is presented in the Fishery Summary section at the beginning of the Oreos report.

2. BIOLOGY

This is presented in the Biology section at the beginning of the Oreos report.

3. STOCKS AND AREAS

This is presented in the Stocks and Areas section at the beginning of the Oreos report.

4. STOCK ASSESSMENT

4.1 Introduction

New assessments for Pukaki Rise black oreo and Pukaki Rise smooth oreo were attempted in 2013 but were rejected by the Working Group and are only briefly discussed here. The previously reported assessments for Southland (OEO 1/OEO 3A) and Bounty Plateau smooth oreo (only MPD results) are repeated.

4.2 Southland smooth oreo fishery

This assessment was updated in 2007 and applies only to the study area as defined in Figure 1 and does not include areas to the north (Waitaki) and east (Eastern canyon) of the main fishing grounds.

This fishery is mostly in OEO 1 on the east coast of the South Island but catches occur at the northern end of the fishery straddle and cross the boundary line between OEO 1 and OEO 3A at 46°S. This is an old fishery with catch and effort data available from 1977–78. Smooth oreo catch from Southland was about 480 t (mean of 2003–04 to 2005–06). There is an industry catch limit of 400 t smooth oreo implemented after the previous (2003) assessment. There were no fishery-independent abundance estimates, so relative abundance estimates from pre- and post-GPS standardised CPUE analyses and length frequency data collected by Ministry (SOP) and industry (ORMC) observers were used.

The following assumptions were made in this analysis.

1. The CPUE analysis indexed the abundance of smooth oreo in the study area of OEO 1/3A.
2. The length frequency samples were representative of the population being fished.
3. The ranges used for the biological values covered their true values.
4. Recruitment was deterministic and followed a Beverton-Holt relationship with steepness of 0.75.
5. The population of smooth oreo in the study area was a discrete stock or production unit.
6. Catch overruns were 0% during the period of reported catch.
7. The catch histories were accurate.
8. The maximum fishing pressure (U_{MAX}) was 0.58.

An age-structured CASAL model employing Bayesian statistical techniques was developed. A two-fishery model was employed with a split into deep and shallow fisheries because of a strong relationship found between smaller fish in shallow water and large fish in deeper water. The boundary between deep and shallow was 975 m. The 2007 analysis used five extra years of catch and observer length frequency data compared to the 2003 assessment. The model was partitioned by the sex and maturity status of the fish and used population parameters previously estimated from fish sampled on the Chatham Rise and Puysegur Bank fisheries. The maturity ogive used was estimated from Chatham Rise research samples.

4.2.1 Estimates of fishery parameters and abundance

Catch history

A catch history (Table 1) was derived using declared catches of OEO from OEO 1 (see table 2 in the Fishery Summary section at the beginning of the Oreos report) and tow-by-tow records of catch from the study area (Figure 1). The tow-by-tow data were used to estimate the species ratio (SSO/BOE) and therefore the SSO taken. It was assumed that the reported landings provided the best information on total catch quantity and that the tow-by-tow data provided the best information on the species and area breakdown of catch.

Table 1: Catch history of smooth oreo from Southland rounded to the nearest 10 t.

Fishing year	Shallow	Deep	Fishing year	Shallow	Deep
1977–78	210	0	1992–93	410	250
1978–79	10	0	1993–94	220	150
1979–80	40	0	1994–95	80	150
1980–81	0	0	1995–96	600	500
1981–82	0	0	1996–97	440	70
1982–83	0	0	1997–98	320	230
1983–84	480	660	1998–99	480	620
1984–85	170	510	1999–00	650	480
1985–86	480	3 760	2000–01	400	610
1986–87	30	160	2001–02	580	1 470
1987–88	130	860	2002–03	130	1 320
1988–89	0	240	2003–04	330	420
1989–90	210	430	2004–05	140	290
1990–91	410	420	2005–06	120	140
1991–92	530	380			

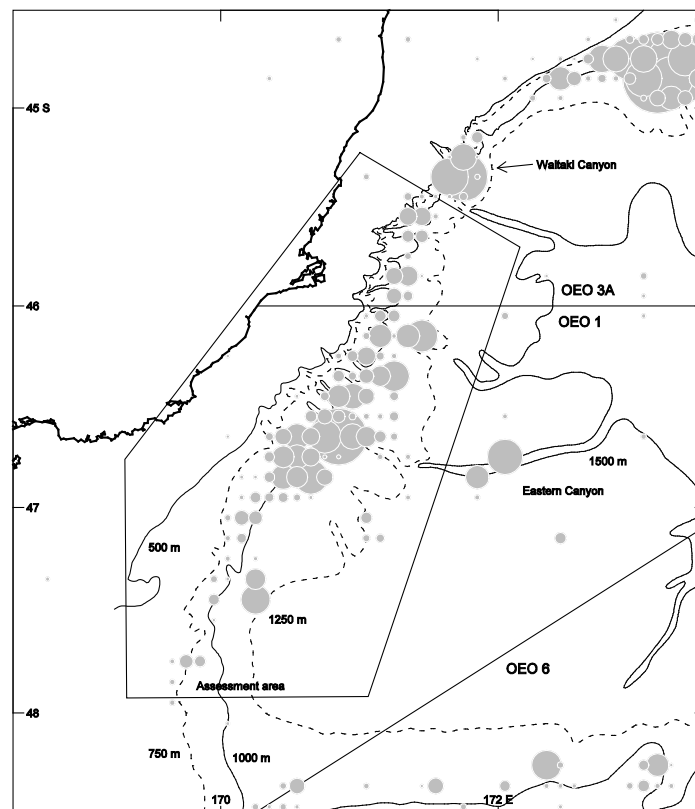

Figure 1: Smooth oreo estimated catch from all years up to (and including) 2005–06. The area was divided into cells that are 0.1 degrees square and catches were summed for each cell. Circles proportional in area to the catch are plotted centred on the cells. Catches less than 10 tonnes per cell are not shown. Circles are layered so that smaller circles are never hidden by larger ones. The assessment area and bottom topography are also shown.

Length data

All SOP records where smooth oreo were measured from within the assessment area are shown in Table 2: 78 samples were shallow and 51 deep. Only 13 shallow and 4 deep samples were collected before 1999–2000 (Table 2). Composite length frequency distributions were calculated for each year. Each sample was weighted by the catch weight of the tow from which the sample was taken. This was modified slightly by estimating the number of fish that would be in a unit weight of catch and multiplying by that.

Table 2: Summary of length frequency data for smooth oreo available for the study area. Year group, year applied, and the total number of length frequency samples for the shallow and deep year groups.

Year group	Year applied	No. of lfs
<u>Shallow</u>		
a=1993–94 to 1997–98	1995–96	13
b=1999–2000	1999–00	30
c=2000–01 to 2001–02	2001–02	22
d=2002–03 to 2005–06	2004–05	13
<u>Deep</u>		
e=1997–98 to 2001–02	2001–02	27
f=2002–03 to 2004–05	2003–04	21

Relative abundance estimates from CPUE analyses

The standardised CPUE analyses used a two part model which separately analysed the tows which caught smooth oreo using a log-linear regression (referred to as the positive catch regression) and a binomial part which used a Generalised Linear Model with a logit link for the proportion of successful tows (referred to as the zero catch regression). The binomial part used all the tows, but considered only whether or not the species was caught and not the amount caught. The yearly indices from the two parts of the analysis (positive catch index and zero catch index) were multiplied together to give a combined index. The pre-GPS data covered the years from 1983–84 to 1987–88, was left unmodified from 2003, and was used as an index of the deep fishery as most fishing in that period was deep (Table 3). The post-GPS data covered 1992–93 to 2005–06 split into shallow and deep fisheries but the indices for the last two years (2004–05, 2005–06) were dropped because catch was constrained by the industry catch limit of 400 t for smooth oreo introduced after the 2003 assessment (Table 4).

Table 3: Smooth oreo pre-GPS combined index estimates by year, and jackknife CV estimates from analysis of all tows in the study area that targeted smooth oreo, black oreo, or unspecified oreo.

Year	Combined index	Jackknife CV (%)
1983–84	1.75	22
1984–85	1.65	29
1985–86	1.19	33
1986–87	0.48	23
1987–88	0.61	27

Table 4: Smooth oreo post-GPS combined index estimates by year, and jackknife CV estimates from analysis of all tows in the study area that targeted smooth oreo, black oreo, or unspecified oreo.

Fishing year	Shallow		Deep	
	Index (kg/tow)	Bootstrap CV (%)	Index (kg/tow)	Bootstrap CV (%)
1992–93	1 489	57	1 401	73
1993–94	956	47	916	53
1994–95	1 521	72	428	121
1995–96	1 173	37	1 862	84
1996–97	511	84	2 117	41
1997–98	1 477	39	502	59
1998–99	939	42	915	50
1999–00	842	44	611	48
2000–01	758	46	385	72
2001–02	573	44	658	53
2002–03	303	48	406	76
2003–04	480	57	719	218

4.2.2 Biomass estimates

Biomass estimates were made based on a Markov Chain Monte Carlo analysis which produced a total of about 1.4 million iterations. The first 100 000 iterations were discarded and every 1000th point was retained, giving a final converged chain of about 1300 points.

Biomass estimates for the base case are given in Table 5 and Figure 2. These biomass estimates are uncertain because of the reliance on commercial CPUE data for abundance indices.

Table 5: Biomass estimates (t) for the base case.

	5%	Median	Mean	95%	CV (%)
Free parameters

Derived quantities					
Current mature biomass (% initial)	19	27	28	41	25
Current selected shallow biomass (% initial)	56	65	65	73	8
Current selected deep biomass (% initial)	12	20	22	36	36

Figure 2: Estimated biomass trajectories from the 2007 base case assessment — mature biomass and selected biomass for the shallow and deep fisheries. Also shown are the CPUE indices from the pre- and post-GPS analysis for the deep fishery (in gray) and the post-GPS analyses for the shallow fishery (in black). CPUE indices are shown with ± 2 s.e. confidence interval indicated by the vertical lines (the post-GPS CPUE data are slightly offset to avoid over plotting). The CPUE data were scaled by catchability coefficients to match the biomass scale.

4.3 Pukaki Rise smooth oreo fishery (part of OEO 6)

A second assessment for this fishery was attempted in 2013, applying only to the assessment area as defined in Figure 3. The first assessment for this fishery was in 2006–07 (Coburn et al 2007; McKenzie 2007). This is the main smooth oreo fishery in OEO 6 with an annual catch in 2011–12 of 290 t, taken mainly by New Zealand vessels, down substantially from previous years (Table 6). There was also a small early Soviet fishery (1980–81 to 1985–86) with mean annual catches of less than 100 t. There were no fishery-independent abundance estimates, so relative abundance estimates from a post-GPS standardised CPUE analysis and length frequency data collected by Ministry and industry observers were considered. Biological parameter values estimated for Chatham Rise and Puysegur Bank smooth oreo were used in the assessment because there are no research data from Pukaki Rise. However, the CPUE analysis was not accepted as an index of abundance for smooth oreo in the Pukaki Rise (OEO 6) assessment area, principally due to the complex temporal and spatial patterns of this fishery and associated fisheries, and the small number of vessels. As a result, the assessment was not accepted by the Working Group, and only catch history, length frequencies and unstandardised catch and effort data are reported here.

Figure 3: The Pukaki Rise fishery assessment area (polygon) abutting the north boundary of OEO 6. The dots show all tows where the target species or catch was OEO, SSO, BOE or ORH, with the red dots being those within the Pukaki assessment area.

4.3.1 Estimates of fishery parameters and abundance

Catch history

A catch history was derived using declared catches of OEO from OEO 6 (table 2 in the “Fishery Summary” section of the Oreos report) and tow-by-tow records of catch from the assessment area (Figure 3). The tow-by-tow data were used to estimate the species ratio (SSO/BOE) and therefore the amount of SSO taken. It was assumed that the reported landings provided the best information on total catch quantity and that the tow-by-tow data provided the best information on the species and area breakdown of catch. There may be unreported catch from before records started, although this is thought to be small. Before the 1983–84 fishing year the species catch data were combined over years to get an average figure that was then applied in each of those early years. For the years from 1983–84 onwards, each year’s calculation was made independently. The catch history used in the population model is given in Table 6.

Table 6: Catch history of smooth oreo from the Pukaki Rise fishery assessment area. Catches are rounded to the nearest 10 t.

Year	Catch	Year	Catch	Year	Catch	Year	Catch
1980–81	30	1988–89	0	1996–97	1 650	2004–05	1 370

						2012–13	136

Length data

Smooth oreo length frequency data collected by observers are available for the years 1997–98 to 2011–12 (Table 7). An in-depth analysis of these data in the previous assessment (covering fishing years 1998–2005) indicated that they were reasonably representative of the fishery in terms of spatial, depth and temporal coverage in those years that had adequate data (Coburn et al 2007). The depths fished by the sampled fleet varied between years so the length data were stratified by depth resulting in shallow (less than 900 m), middle (900–990 m) and deep strata (greater than 990 m). The data from adjacent years were also grouped because some years had few samples. The resulting length frequencies are shown in Figure 4. There is a trend towards a flatter distribution over the last three grouped distributions (2000–01, 02, and 03–05).

Table 7: Summary of length frequency data for smooth oreo available for the assessment area. The table shows the number of tows sampled by year, the sample source, and the year group. -, no data.

Year	Year group	Number of tows sampled		
		ORMC	SOP	All

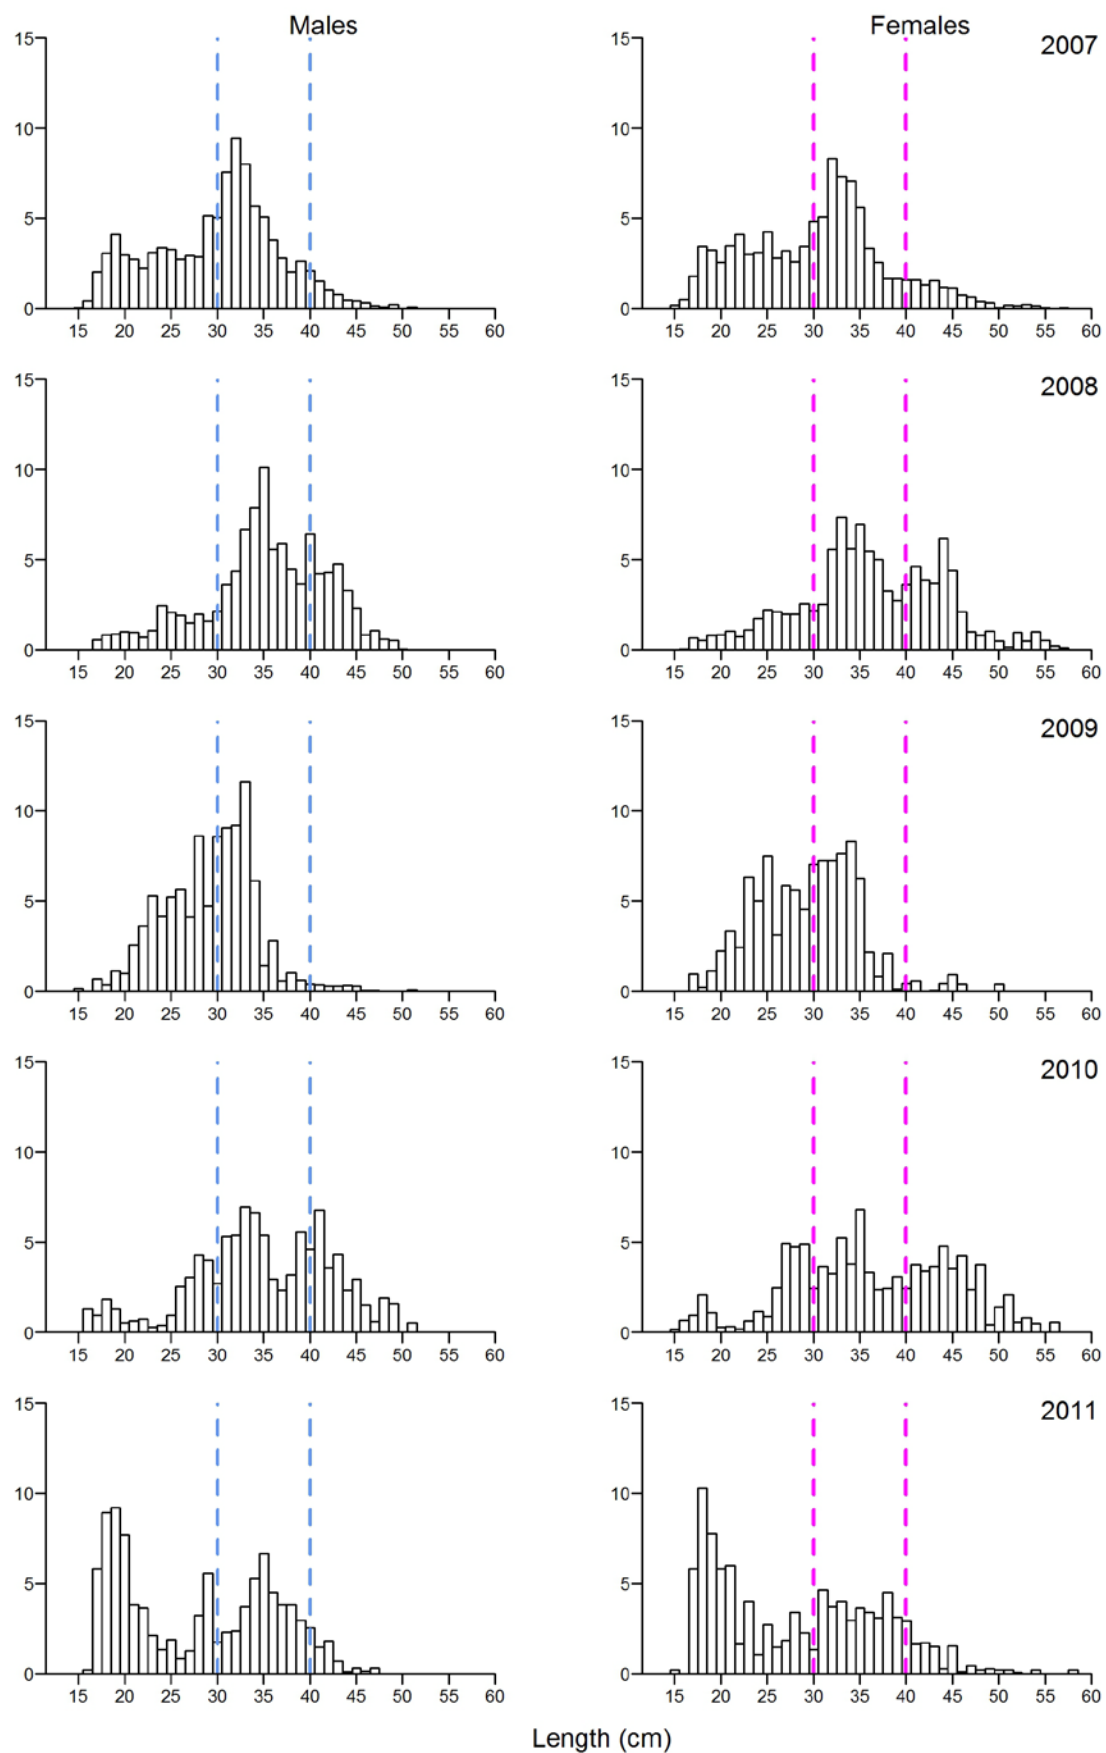

Figure 4 [Continued].

Catch and effort data

Core vessels for the fishery were defined in order to develop a standardised CPUE series, but the standardised series was rejected by the Working group. Unstandardised catch and effort data are presented in Table 8.

Table 8: Catch and effort data for vessels with three or more consecutive years with at least 10 records from 1995–96 to 2011–12.

	No. of tows	No. of vessels	Estimated catch (t)	Mean t/tow	Zero catch tows (%)	SSO target (%)
1996	193	2	810	4.20	-	6
1997	322	3	1 270	3.90	4	4

2012	397	2	260	0.70	10	12

4.4 Bounty Plateau smooth oreo fishery (part of OEO 6)

The first assessment for this fishery was developed in 2008 and applies only to the study area as defined in Figure 5. There were no fishery-independent abundance estimates, so relative abundance estimates from a post-GPS standardised CPUE analysis and length frequency data collected by Ministry (SOP) and industry (ORMC) observers were considered. Biological parameter values estimated for Chatham Rise and Puysegur Bank smooth oreo were used in the assessment because there are no research data from Bounty Plateau.

The following assumptions were made in this analysis.

1. The CPUE analysis indexed the abundance of smooth oreo in the Bounty Plateau (OEO 6) assessment area.
2. The length frequency samples were representative of the population being fished.
3. The biological parameters values used (from other assessment areas) are close to the true values.
4. Recruitment was deterministic and followed a Beverton & Holt relationship with steepness of 0.75.
5. The population of smooth oreo in the assessment area was a discrete stock or production unit.
6. Catch overruns were 0% during the period of reported catch.
7. The catch histories were accurate.
8. The maximum exploitation rate (E_{MAX}) was 0.58.

Data inputs included catch history, relative abundance estimates from a standardised CPUE analysis, and length data from SOP and ORMC observers. The observational data were incorporated into an age-based Bayesian stock assessment (CASAL) with deterministic recruitment to estimate stock size. The stock was considered to reside in a single area, with a partition by sex. Age groups were 1–70 years, with a plus group of 70+ years.

The length-weight and length-at-age population parameters are from fish sampled on the Chatham Rise and Puysegur Bank fisheries (table 1 of the “Biology” section of the Oreos report). The natural mortality estimate is based on fish sampled from the Puysegur Bank fishery. The maturity ogive is from fish sampled on the Chatham Rise, and the age at which 50% are mature is between 18 and 19 years for males and between 25 and 26 years for females.

4.4.1 Estimates of fishery parameters and abundance

Catch history

Table 9: Catch history (t) of smooth oreo from the Bounty Plateau fishery assessment area. Catches are rounded to the nearest 10 t.

Year	Catch	Year	Catch
1983–84	620	1996–97	610
1984–85	0	1997–98	650
1985–86	0	1998–99	1 200
1986–87	0	1999–00	870
1987–88	10	2000–01	550
1988–89	0	2001–02	980
1989–90	0	2002–03	1 530
1990–91	20	2003–04	1 420
1991–92	0	2004–05	2 190
1992–93	110	2005–06	1 790
1993–94	490	2006–07	670
1994–95	1 450	2007–08	670
1995–96	900		

A catch history was derived using declared catches of oreo from OEO 6 (table 2 in the “Fishery Summary” section of the Oreos report) and tow-by-tow records of catch from the assessment area (Figure 5). The tow-by-tow data were used to estimate the species ratio (SSO/BOE) and therefore the SSO taken. The catch history used in the population model is given in Table 9.

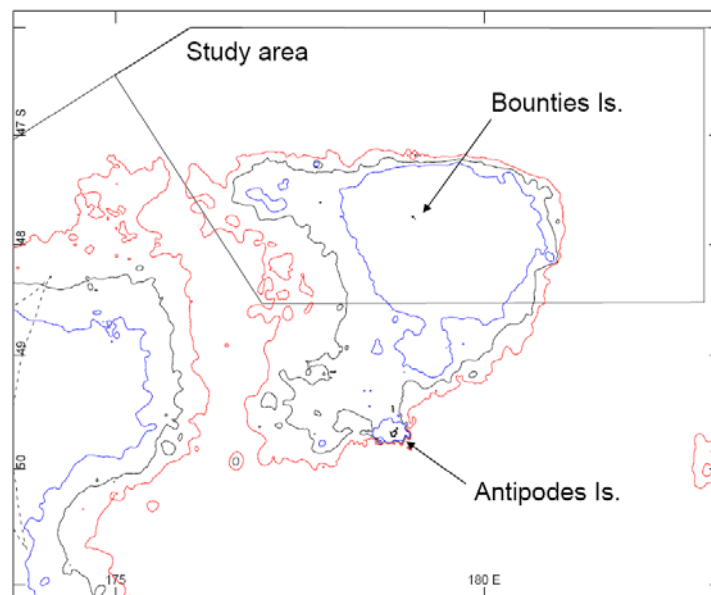

Figure 5: The Bounty Plateau fishery assessment study area.

Length data

Smooth oreo length frequency data collected by SOP and ORMC observers are available from 1991–92. An in-depth analysis indicated that these data were reasonably representative of the fishery in terms of spatial, depth and temporal coverage in those years that had adequate data. Length frequencies were based on tows from the core area (a subset of the study area where about 80% of the catch is taken). The data from adjacent years were grouped because some years had few samples (Table 10). The resulting length frequencies are shown in Figure 6. In the final model runs the 1994–95 year of the length frequency series was omitted as it contained very few samples.

Table 10: Core length analysis Year group, year applied and the number of length frequency samples. Smooth oreo sample catch weight, fishery catch and sample catch as percentage of the fishery.

Year group	Year applied	No. of lfs	Catch sampled (t)	Fishery catch (t)	% fishery
1991–92 to 1995–96	1994–95	7	88	1 505	6
1998–99 to 1999–2000	1998–99	30	246	1 121	22
2000–2001 to 2002–03	2001–02	25	398	2 261	18
2003–04 to 2004–05	2004–05	29	261	2 280	11
2005–06	2005–06	32	379	1 121	34
2006–07 to 2007–08	2006–07	17	168	494	34

Relative abundance estimates from CPUE analyses

The small early Soviet fishery had too few data for a standardised CPUE analysis. The standardised CPUE analysis was, therefore, from the New Zealand vessel fishery and only included data from those vessels that had fished at least three years. Just a single vessel puts in significant continuous effort from 1995–2007, with the rest of the vessels' effort confined to mainly either 1995–2000 (early) or 2001–2007 (late). Because of this, in addition to the single standardised CPUE covering the entire time period, two separate standardised CPUE indices were calculated covering the early and late periods. The final indices are shown in Tables 11 and 12.

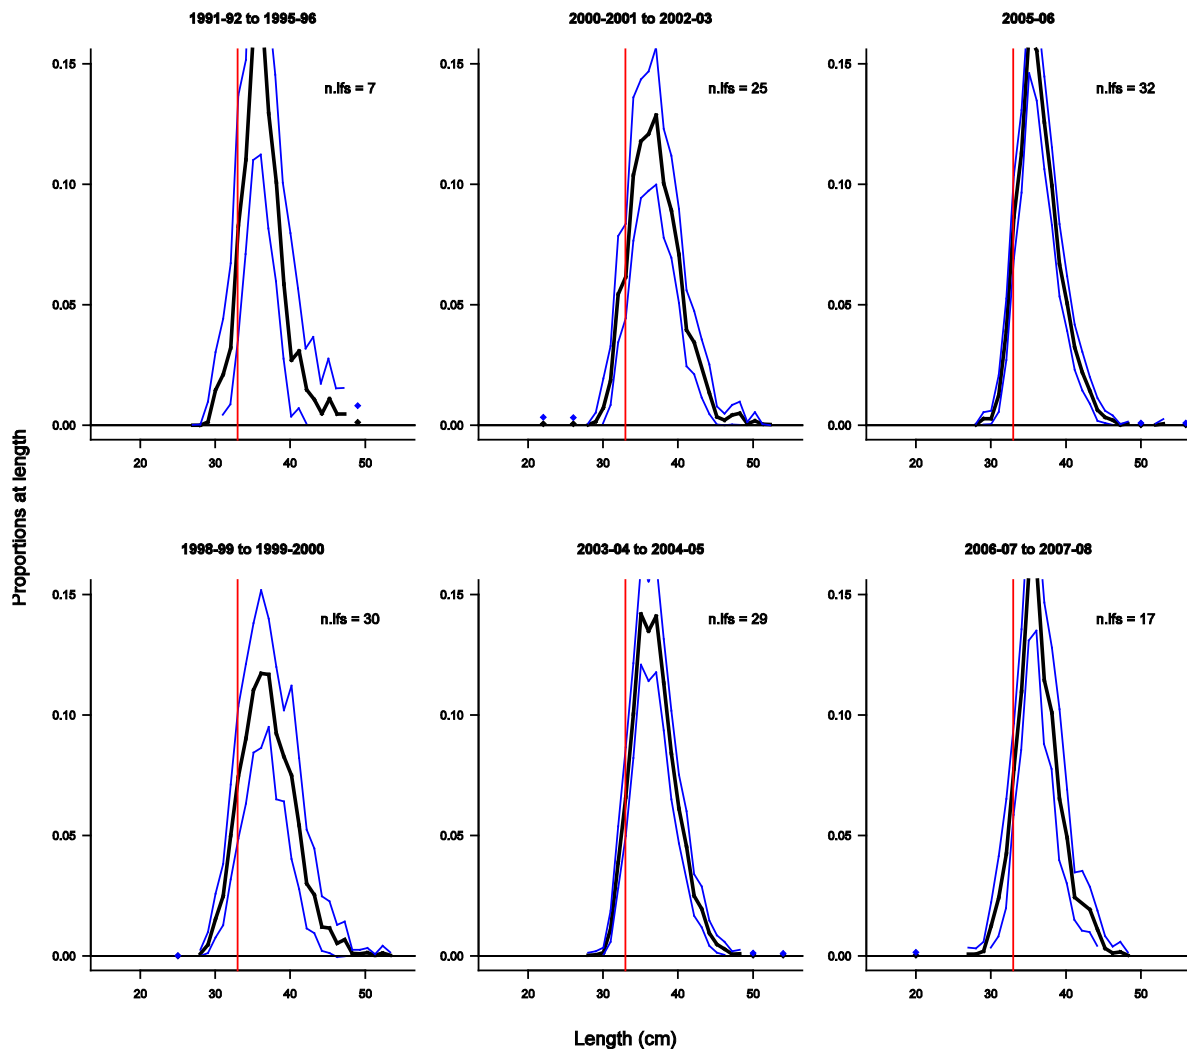

Figure 6: Length frequency distribution plots for core data only (thick lines) with 95% confidence interval (thin lines).

Table 11: Early and late period CPUE combined index estimates by year, and bootstrap CV estimates.

Year Early	Kg/tow	CV	Late period	Kg/tow	CV
1995–96	3551	0.423	2000–01	850	0.487
1996–97	3322	0.496	2001–02	2976	0.274
1997–98	2306	0.980	2002–03	1489	0.243
1998–99	781	0.391	2003–04	1727	0.260
1999–2000	1536	0.306	2004–05	1604	0.227
			2005–06	1386	0.310
			2006–07	966	0.232

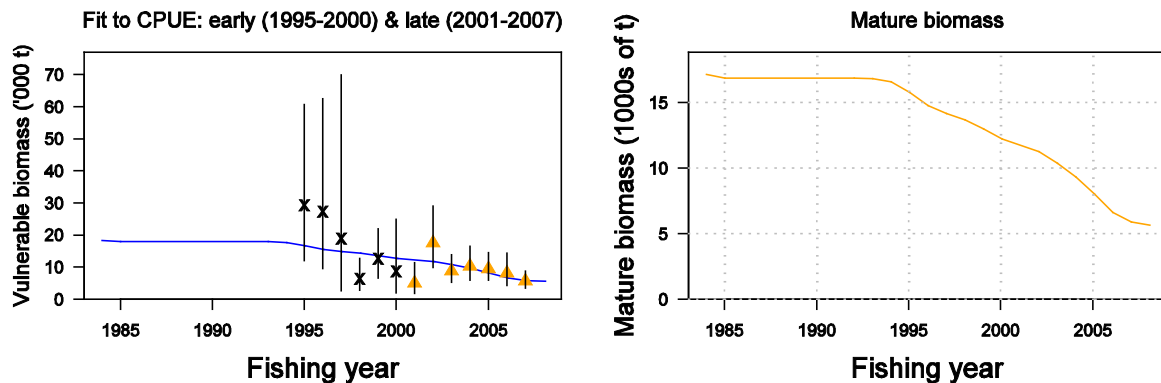

Table 12: Single period CPUE combined index estimates by year, and bootstrap CV estimates.

Year	Kg/tow	CV
1995–96	7472	0.286
1996–97	4453	0.735
1997–98	3366	1.264
1998–99	1444	0.406
1999–2000	2835	0.286
2000–01	2817	0.436
2001–02	632	0.680
2002–03	1973	0.663
2003–04	1296	0.615
2004–05	1284	0.445
2005–06	1289	0.563
2006–07	1056	1.200

4.4.2 Biomass estimates

In all preliminary model runs the length-frequency data series were not well fitted, and gave a strong but contrasting biomass signal relative to the CPUE indices. Therefore, for final model runs, the length frequency data was down-weighted by using just the 1999 length frequency.

The base case model used early and late period CPUE indices, and the 1999 length frequency data. Current mature biomass was estimated to be 33% of a virgin biomass of 17 400 t (Figure 7).

**Figure 7: Model run showing the MPD fit to the CPUE data (vertical lines are the 95% confidence intervals for the indices) and the trajectory of mature biomass.**

Two sensitivity model runs were carried out with the 1999 length frequency data dropped from the model, but retaining the fishery selectivity estimated using the length data. The first model run used the early and late period CPUE indices and current biomass was estimated to be 39% of a virgin biomass of 19 300 t. The second model run used the single CPUE series covering the same period and current biomass was estimated to be 17% of a virgin biomass of 13 900 t. No MCMC runs were carried out with the base case model as the sensitivity runs showed that the assessment was quite different if the CPUE analysis was not split into two series.

Biomass estimates are uncertain because of the reliance on commercial CPUE data, the use of biological parameter estimates from other oreo stocks, and because of contrasting biomass signals from using either a single or split CPUE indices.

4.4.3 Projections

No projections were made because of the uncertainty in the assessment.

4.5 Pukaki Rise black oreo stock (part of OEO 6)

A second assessment for this fishery was attempted in 2013, applying only to the assessment area as defined in Figure 8. The first assessment for this fishery was in 2009 (Doonan et al 2010). This is currently the largest black oreo fishery in the New Zealand EEZ with both current (2011–12) and mean (1994–95 to 2011–12) annual catches of 1900 t, but with annual catches of 2800–3400 t between 2005–06 and 2009–10. There was an early Soviet and Korean fishery (1980–81 to 1984–85) with mean annual catches of about 1700 t. Fishery-independent abundance estimates were not available, so a series of relative abundance indices, based on an analysis of post-GPS standardised CPUE, was developed. Length frequency data collected by Ministry (SOP) and industry (ORMC) observers were included in the model. The assessment used biological parameter values estimated for Chatham Rise and Puysegur Bank black oreo because no biological data from Pukaki Rise are available. As stated above, the Pukaki Rise smooth oreo CPUE was thought to be unreliable until further investigations have been conducted. Since the black oreo fishery is in the same area, the Working Group determined that the black oreo CPUE analysis also could not be accepted as an index of abundance of black oreo in the Pukaki Rise (OEO 6) assessment area, and as a result the assessment was rejected. Therefore, only catch history, length frequencies and unstandardised catch and effort data are reported here.

4.5.1 Estimates of fishery parameters and abundance

Catch history

A catch history for black oreo was derived (Table 13) using declared catches of OEO from OEO 6 (table 2 in the “Fishery summary” section of the Oreos report) and tow-by-tow records of catch from the assessment area (Figure 8). The catch history used in the assessment is given in Table 13.

Table 13: Catch history (t) of black oreo from the Pukaki Rise fishery assessment area.

Year	Catch	Year	Catch	Year	Catch
1978–79	17	1990–91	15	2002–03	1 701
1979–80	5	1991–92	27	2003–04	1 530
1980–81	283	1992–93	27	2004–05	1 588

1982–83	1 084	1994–95	242	2006–07	3 434
1983–84	1 150	1995–96	1 352	2007–08	3 346
1984–85	1 704	1996–97	2 413	2008–09	2 818
1985–86	46	1997–98	2 244	2009–10	3 093
1986–87	0	1998–99	1 181	2010–11	1 641
1987–88	0	1999–00	1 061	2011–12	1 671
1988–89	0	2000–01	1 158		
1989–90	0	2001–02	988		

Length data

Black oreo length frequency data collected by SOP and ORMC observers are available from 1996–97 to 2011–12 (Table 14). An analysis indicated that there was a trend in fish size across years (with smaller mean lengths in more recent years) and with depth (deeper fish being larger). The length data were considered to be representative of the fishery in terms of the spatial, depth, and temporal coverage for those years that had adequate data. The length data were stratified into two depth bins: shallow (less than 900 m), and deep (greater than 900 m). Length data from adjacent years were grouped because of the low number of samples in some years (Figure 9). There is no trend in mean length over the first six year-groups, but fish sizes appear to be generally smaller in the later year-groups, with the mode of the distributions shifting to the left between 2005–06 and 2007–08.

Table 14: Summary of length frequency data for black oreo available from the assessment area. The table shows the number of tows sampled by year, the sample source, and the year group.

Year	Year group	Number of tows sampled		
		SOP	ORMC	All
1996–97	97–98	7	0	7
1997–98	97–98	25	0	25

Total		477	134	611

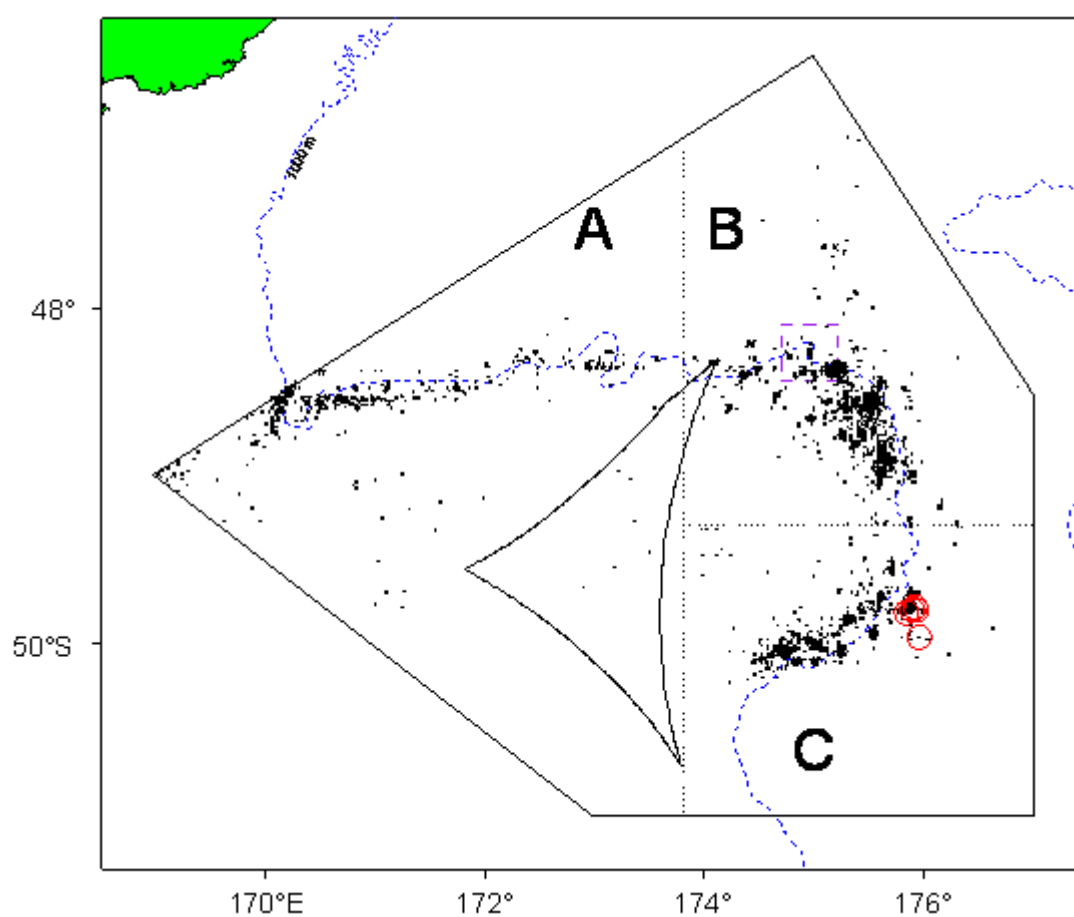

Figure 8: The Pukaki Rise fishery black oreo assessment area (polygon) abutting the boundary of OEO 6/OEO 1 in the north-west. The dots show tow positions where black oreo catch was reported between 1980–81 and 2011–12. A, B, and C are the three areas defined in the standardised CPUE analysis.

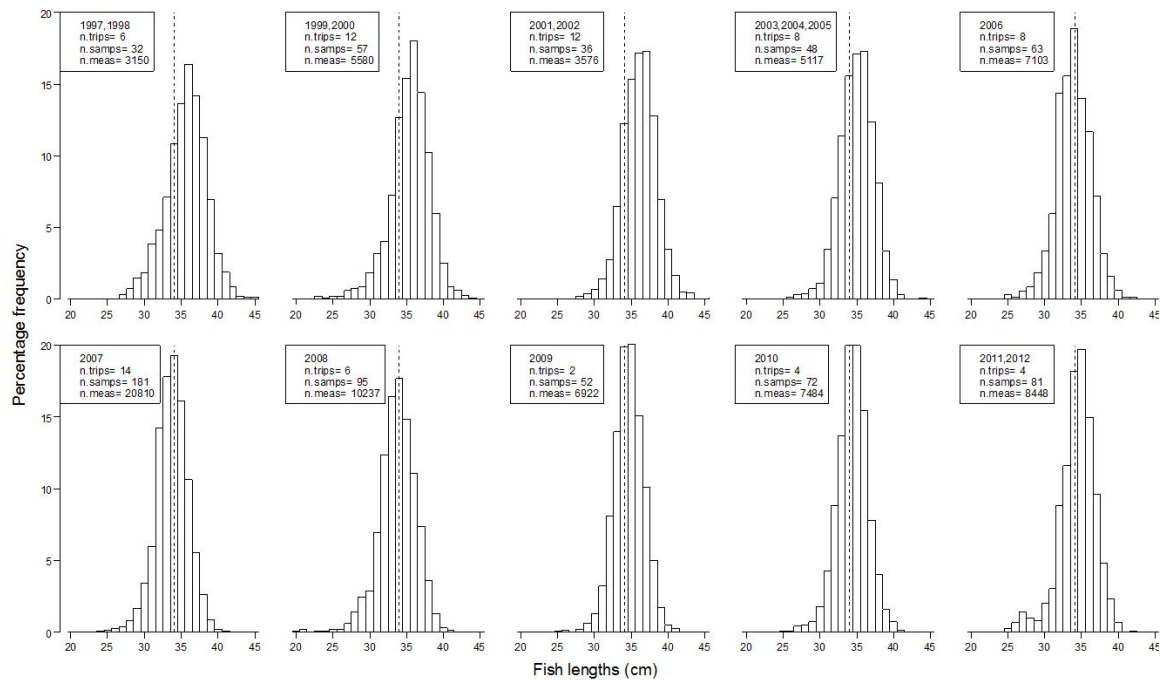

Figure 9: Observer length frequencies for Pukaki Rise black oreo, stratified by depth (see text), and grouped by years (in the legends 1997=1996–97 etc.). The vertical dashed lines indicate the approximate overall mean length as an aid to comparing the distributions.

Catch and effort data

The fishery taking Pukaki Rise black oreo divides into two distinct periods: a pre-GPS period 1980–81 to 1984–85 when much of the catch was taken by Soviet and Korean vessels, and a post-GPS period, 1995–96 to 2011–12 when most of the catch was taken by New Zealand vessels. The intervening period was characterised by low catches and the introduction of GPS technology in the fleet. Standardisation of CPUE for the pre-GPS period was attempted but rejected due to poor linkage of vessels across years and the shifting of fishing effort between areas. For the post-GPS period, the Working Group rejected CPUE as an index of abundance because of the variability in recorded target species over time and space in the overlapping Pukaki fisheries for black oreo, smooth oreo, and orange roughy. The Working Group believed that recording of target species in these fisheries was likely to have been inconsistent between vessels and skippers over time and that the practice of separately examining these fisheries according to recorded target species was inappropriate. Unstandardised catch and effort data for defined core vessels are presented in Table 15.

Table 15: Catch and effort data for vessels fishing in the eastern areas (B and C in Figure 8) with a minimum of 15 successful tows for black oreo in at least three years from 1995–96 to 2011–12.

Year	No. of	CPUE	CV	Year	No. of	CPUE	CV
1995–96	63	1.94	0.09	2004–05	309	0.73	0.13

4.5.2 Biomass estimates

No biomass estimates are reported.

4.5.3 Yield estimates and projections

No yield estimates were made.

No projections were made because the assessment was not accepted by the Working Group.

4.6 Other oreo fisheries in OEO 1 and OEO 6

4.6.1 Estimates of fishery parameters and abundance

Relative abundance estimates from trawl surveys

Two comparable trawl surveys were carried out in the Puysegur area of OEO 1 (TAN9208 and TAN9409). The 1994 oreo abundance estimates are markedly lower than the 1992 values (Table 16).

4.6.2 Biomass estimates

Estimates of virgin and current biomass are not yet available.

4.6.3 Yield estimates and projections

MCY cannot be estimated because of the lack of current biomass estimates for the other stocks.

CAY cannot be estimated because of the lack of current biomass estimates for the other stocks.

4.6.4 Other factors

Recent catch data from this fishery may be of poor quality because of area misreporting.

Table 16: OEO 1. Research survey abundance estimates (t) for oreos from the Puysegur and Snares areas. N is the number of stations. Estimates for smooth oreo were made based on a recruited length of 34 cm TL. Estimates for black oreo were made using knife-edge recruitment set at 27 cm TL.

Smooth oreo					
Puysegur area (strata 0110–0502)					
	Mean biomass	Lower bound	Upper bound	CV (%)	N
1992	1 397	736	2 058	23	82
1994	529	86	972	41	87
Snares area (strata 0801–0802)					
	Mean biomass	Lower bound	Upper bound	CV (%)	N
1992	2 433	0	5 316	59	8
1994	118	0	246	54	7
Black oreo					
Puysegur area (strata 0110–0502)					
	Mean biomass	Lower bound	Upper bound	CV (%)	N
1992	2 009	915	3 103	27	82
1994	618	0	1 247	50	87
Snares area (strata 0801–0802)					
	Mean biomass	Lower bound	Upper bound	CV (%)	N
1992	3 983	0	8 211	53	8
1994	1 564	0	3 566	64	7

5. STATUS OF THE STOCKS

Stock Structure Assumptions

Oreos in the OEO 1 and 6 FMAs are managed as a single stock but assessed as four separate stocks, separated by species and geography.

The Southland smooth oreo stock is based along the east coast of the South Island in OEO 1 but extends slightly into OEO 3. It does not include the Waitaki and Eastern canyon areas but is likely to have some level of mixing with other smooth oreo fishstocks. The Pukaki Rise smooth oreo stock comprises the major part of OEO 6 stocks and is centred on its namesake. Some mixing with other smooth oreo fishstocks is thought to occur. The Bounty Plateau smooth oreo stock is located across the Bounty Plateau and the Bounty Islands. Some mixing is thought to occur with other smooth oreo fishstocks.

The Pukaki Rise black oreo stock is the main black oreo fishstock in OEO 6 and the largest black oreo fishstock in the New Zealand EEZ. It extends the entire length of the Rise towards OEO 1. It is assessed separately to other fishstocks but managed as a part of OEO 6. Black oreo on the Pukaki Rise are thought to be non-mixing with other black oreo fishstocks.

- OEO 1 and OEO 3A Southland (Smooth Ore)

Stock Status	
Year of Most Recent Assessment	2007
Assessment Runs Presented	One base case only
Reference Points	Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold:
Status in relation to Target	B_{2007} was estimated at 27% B_0 , Unlikely (< 40%) to be at or above the target.
Status in relation to Limits	B_{2007} was estimated to be Unlikely (< 40%) to be below the Soft Limit and Very Unlikely (< 10%) to be below the Hard Limit.
Status in relation to Overfishing	-

Historical Stock Status Trajectory and Current Status

Predicted biomass trajectories for the 2007 base case assessment— mature biomass and selected biomass for the shallow and deep fisheries. Also shown are the CPUE indices from the pre- and post-GPS analysis for the deep fishery (in gray) and the post-GPS analyses for the shallow fishery (in black). CPUE indices are shown with ± 2 s.e. confidence interval indicated by the vertical lines (the post-GPS CPUE data are slightly offset to avoid over plotting). The CPUE data were scaled by catchability coefficients to match the biomass scale.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass has been declining at a steady rate since the late 1980s.
Recent Trend in Fishing Mortality or Proxy	Unknown
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	None because of assessment uncertainty.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown
Probability of Current Catch or TACC causing Overfishing to continue or to commence	-

Assessment Methodology		
Assessment Type	Type 1 - Quantitative Stock Assessment	
Assessment Method	Age-structured CASAL model with Bayesian estimation of posterior distributions.	
Assessment Dates	Latest assessment: 2007	Next assessment: Unknown
Overall assessment quality rank	-	
Main data inputs (rank)	- Length-frequency data collected by SOP and ORMC observers - A second, earlier fishery based on Soviet vessels was included in the assessment using historical catch data. - Standardised CPUE indices were derived from the historical and modern datasets.	
Data not used (rank)	-	
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- Scarcity of observer length frequency data - Poor quality area catch data due to significant misreporting - Lack of fishery-independent abundance estimates creates reliance on commercial CPUE data.	

Qualifying Comments
-

Fishery Interactions
Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries and in smaller numbers in hoki target fisheries. Target fisheries for oreos do exist, with main bycatch being orange roughy, rattails and deepwater sharks and rays. Other bycatch species recorded include seabirds and deepwater corals.

- OEO 6 Pukaki Rise (Smooth Oreo)**

Stock Status	
Year of Most Recent Assessment	2013
Assessment Runs Presented	CASAL assessment based on CPUE rejected

Status in relation to Target	Unknown
Status in relation to Limits	Unknown
Status in relation to Overfishing	Unknown

Historical Stock Status Trajectory and Current Status

-

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass is likely to have been declining since 1996.
Recent Trend in Fishing Intensity or Proxy	Unknown
Other Abundance Indices	CPUE has steadily declined.
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis

Stock Projections or Prognosis	No projections were made due to the uncertainties in the assessment.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: Unknown Hard Limit: Unknown
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Unknown

Assessment Methodology and Evaluation

Assessment Type	Type 1 – Quantitative Stock Assessment, but rejected.	
Assessment Method	CASAL assessment based on CPUE (rejected)	
Assessment Dates	Latest assessment: 2013	Next assessment: Unknown
Overall assessment quality rank	3 – Low Quality	
Main data inputs (rank)	-	
Data not used (rank)	Commercial CPUE	3 – Low Quality: does not track stock biomass
Changes to Model Structure and Assumptions	-	
Major Sources of Uncertainty	- Lack of fishery-independent biomass estimates creates reliance on commercial CPUE data. - Lack of biological parameters specific to Smooth Oreo in the target area – data from Chatham Rise/Puysegur Bank had to be substituted instead.	

Qualifying Comments

Further investigations into CPUE are required.

Fishery Interactions

Both species of oreo are sometimes taken as bycatch in orange roughy target fisheries and in smaller numbers in hoki target fisheries. Target fisheries for oreos do exist, with main bycatch being orange roughy, rattails and deepwater sharks. Low productivity bycatch species include deepwater sharks and rays. Protected species interactions occur with seabirds and deepwater corals.

1. FISHERY SUMMARY

1.1 Commercial fisheries

Paddlecrabs were introduced into the QMS from 1 October 2002 with recreational and customary non-commercial allowances, TACCs and TACs summarised in Table 1.

Table 1: Recreational and Customary non-commercial allowances, TACCs and TACs for paddle crabs, by Fishstock.

Fishstock	Recreational Allowance	Customary non-Commercial Allowance	TACC	TAC
PAD 1	20	10	220	250
PAD 2	10	5	110	125
PAD 3	8	2	100	110
PAD 4	4	1	25	30
PAD 5	4	1	50	55
PAD 6	0	0	0	0
PAD 7	4	1	100	105
PAD 8	4	1	60	65
PAD 9	20	10	100	130
PAD 10	0	0	0	0

Commercial interest in paddle crabs was first realised in New Zealand in 1977–78 when good numbers of large crabs were caught off Westshore Beach, Napier in baited lift and set-pots. Annual catches have varied, mainly due to marketing problems, and estimates are likely to be conservative. Landings increased in the early fishery, from 775 kg in 1977 to 306 t in 1985, and 403 t in 1995–96 but have since generally decreased. Paddle crabs are known to be discarded from inshore trawl operations targeting species such as flatfish, and this may have resulted in under-reporting of catches. Crabs are marketed live, as whole cooked crabs, or as crab meat. Attempts were made to establish a soft-shelled crab industry in New Zealand in the late 1980s.

Bycatch is commonly taken during trawl, dredge and setnetting operations. Catch rates vary considerably with method, season and area, and there is no clear seasonal trend to paddle crab landings. It is likely that catches are related to the availability of fishers and/or market demands. Commercial landings from 1989–90 until the present are shown in Table 2, while Figure 1 shows the historical landings and TACC for the six main PAD stocks.

1.2 Recreational fisheries

Paddle crabs are taken as a bycatch of beach and estuarine seining and in setnets throughout much of their geographical range. A National Panel Survey of recreational fishers was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Harvest estimates (in number of paddle crabs) are given in Table 3 (from Wynne-Jones et al 2014, no estimates of mean weight were available from ramp surveys). These estimates are all very uncertain because of the small number of fishers reporting catch.

Table 3: Recreational harvest estimates for blue mackerel stocks (Wynne-Jones et al 2014). No estimates of mean weights were available to convert catches to tonnes.

Stock	Year	Method	Number of fish	Total weight (t)	CV
PAD 1	2011/12	Panel survey	2 003	-	0.86
PAD 2	2011/12	Panel survey	827	-	1.02
PAD 3	2011/12	Panel survey	1 768	-	1.01
PAD 5	2011/12	Panel survey	2 532	-	1.02
PAD 8	2011/12	Panel survey	2 225	-	0.71
PAD total	2011/12	Panel survey	9 354	-	0.43

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

There is no quantitative information on the current level of customary non-commercial catch.

1.4 Illegal catch

There is no quantitative information available on the current level of illegal catch.

1.5 Other sources of mortality

There is no quantitative information available on other sources of mortality, although unknown quantities of paddle crabs have been discarded from commercial fishing operations such as the inshore trawl, setnet and dredge fisheries.

2. BIOLOGY

The paddle crab is found off sandy beaches, and in harbours and estuaries throughout mainland New Zealand, the Chatham Islands, and east and south Australia. They are abundant from the intertidal zone to at least 10 m depth, although they do occur in much deeper water. Paddle crabs are mainly active in early evening or at night, when they move into the shallow intertidal zone to feed.

Paddle crabs are versatile and opportunistic predators. They feed mainly on either molluscs or crustaceans, but also on polychaetes, several fish species, cumaceans, and occasionally on algae. A high proportion of the molluscs eaten are *Paphies* species. These include: tuatua (*P. subtriangulata*); pipi (*P. australis*); and toheroa (*P. ventricosa*). The burrowing ghost shrimp *Callinassa filholi*, isopods and amphipods are important crustacean prey items. Cannibalism is common, particularly on small crabs and during the winter moulting season.

Anecdotal information suggests there has been a significant increase in paddle crab numbers since the 1970s. Concern has been expressed as to the impact of an increased number of paddle crabs on bivalve shellfish stocks in coastal waters. Feeding studies have shown that although paddle crabs do eat large adult toheroa and other shellfish, they more usually eat bivalve shellfish spat which are found in abundance.

Mating generally occurs during winter and spring (May to November) in sheltered inshore waters. Female paddle crabs can only mate when they are soft-shelled. Male crabs protect and carry pre-moult females to ensure copulation. Female crabs are thought to migrate to deeper water to spawn over the warmer months

PADDLE CRABS (PAD)

(September to March). After spawning the eggs are incubated until they hatch. *Ovalipes catharus* has an extended larval life characterised by eight zoea stages and a (crab-like) megalopa. The larvae are thought to live offshore in deeper water, migrating inshore in the megalopa stage to settle from January to May.

Two spawning mechanisms have been observed in *O. catharus*. In Wellington, Tasman Bay, and Canterbury, spawning does not appear to be synchronised and females may spawn several times during the season (non-synchronous spawning). In Blueskin Bay, Otago, paddle crabs are group-synchronous, with one clutch of eggs developing to maturity over winter, and spawned from September to February.

Annual fecundity is determined by the number of eggs per brood (brood fecundity) and the number of broods per year. Both these parameters are size dependent and highly variable. Brood fecundity estimates vary considerably geographically from between 82 000–638 000 in Wellington waters, to 100 000–1 200 000 in Canterbury waters, and 931 000–2 122 807 in Otago waters. The number of broods per year also varies geographically from 1.2–3.3 in Wellington waters, to 1.2–2.2 in Canterbury waters, and 1 brood per year in Otago waters (group synchronous spawning).

O. catharus is a relatively large and fast growing species of *Ovalipes*. In Canterbury waters, paddle crabs reach a maximum size of 130 mm carapace width (CW - males only) after 13 postlarval moults and 3 to 4 years after settlement. Other studies have reported maximum sizes up to 150 mm CW. In Wellington waters, crabs of approximately 100 mm carapace width, of either sex, would be at least 3 years old, while larger crabs could be 4 or 5 years old.

The differences in growth rate, size at first maturity, and fecundity (particularly the number of broods) appear to be largely environmentally regulated. At lower temperatures and higher latitudes, paddle crabs grow slower, mature at a larger size, have a shorter breeding season, and produce fewer broods per year.

Estimates of biological parameters relevant to stock assessment are presented in Table 4.

Table 4: Estimates of biological parameters.

Fishstock		Estimate		Source	
<u>1. Natural mortality (females only)</u>

Canterbury (QMA 3)	a	b	a		b
	-3.32	2.79	-3.46		2.89

3. STOCKS AND AREAS

It is not known whether biologically distinct stocks occur, although this seems unlikely given that the species is found throughout New Zealand waters, and from tagging experiments, appears to be highly migratory. There is probably also widespread larval dispersal as larvae spend two months offshore in deeper water (to at least 700 m). Genetically distinct populations may occur in isolated areas such as the Chatham Islands.

4. STOCK ASSESSMENT

4.1 Estimates of fishery parameters and abundance

None are available at present.

4.2 Biomass estimates

No estimates of current or virgin biomass are available. The landings, CPUE, and area data are considered too unreliable or incomplete to allow modelling.

4.3 Yield estimates and projections

MCY cannot be estimated.

CAY cannot be estimated because of the lack of current biomass estimates.

5. STATUS OF THE STOCKS

Estimates of current and reference biomass are not available. Landings have fluctuated significantly in most QMAs, mainly due to market variations. Paddle crabs are abundant throughout most of their range and the fishery is probably only lightly exploited.

PARORE (PAR)*(Girella tricuspidata)*

Parore

**1. FISHERY SUMMARY**

Parore was introduced into the Quota Management System (QMS) on 1 October 2004 with the TACs, TACCs and allowances shown in Table 1.

Table 1: TACs (t), TACCs (t) and allowances (t) for parore.

Fishstock	Recreational Allowance	Customary non-commercial Allowance	Other sources of mortality	TACC	TAC
PAR 1	6	3	4	61	74
PAR 2	1	1	0	2	4
PAR 9	2	1	1	21	25
PAR 10	0	0	0	0	0
Total	9	5	5	84	103

1.1 Commercial fisheries

Parore is principally caught as a bycatch in the grey mullet, flatfish and trevally setnet fisheries in northern New Zealand. Most of the catch comes from eastern Northland and the Firth of Thames (FMA 1) and the Kaipara and Manukau Harbours (FMA 9) (Figure 1). Highest catch rates occur during September to October. Few parore are caught in the other FMAs.

Historical estimated and recent reported parore landings and TACCs are shown in Tables 2, 3 and 4.

Fishers may confuse the codes PAR (parore) and POR (porae) when reporting catches, but given that both species occur in shallow northern waters, misreporting is difficult to discern.

PARORE (PAR)

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns: Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings

Figure 1: Reported commercial landings and TACC for the two main PAR stocks. From top PAR 1 (Auckland East) and PAR 9 (Auckland West).

1.2 Recreational fisheries

Little information is available on the recreational catch of parore but some will be taken in northern areas as a bycatch when targeting other species such as snapper, trevally, and mullet. It is thought these catches are most likely taken by setnetting, with some opportunistic targeting by spear fishers. Telephone-diary surveys in 1994, 1996, and 2000 did not provide estimates of recreational catches, and the national panel survey identified catches only in PAR 1 (an estimated 4328 fish with a CV of 0.50, Wynne-Jones et al 2014). A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary non-commercial fisheries

There is no quantitative information on customary harvest levels of parore. Customary fishers are likely to catch small quantities of parore when targeting other species such as snapper, trevally, and mullet. Parore is considered to be a low value customary species and current catches are likely to be low.

2. BIOLOGY

Parore (*Girella tricuspidata*) occur along both east and west coasts of the North Island, from North Cape to Cook Strait (Anderson et al 1998). It has not been recorded around the Chatham Islands. They usually occur in schools, ranging from half a dozen to several hundred individuals. Although there is evidence that large individuals display territorial behaviour on some reef systems, work in Australia has shown that parore are capable of moving distances of hundreds of kilometres (Pollock 1981).

PARORE (PAR)

Parore grow to a maximum size of at least 600 mm, but most adult fish are around 300–400 mm in length. The maximum age for this species on the North Island east coast, as estimated by scale ring counts (validated by seasonal increments), is 10 years (Morrison 1990). As scales tend to provide underestimates of the age of older fish, maximum age could be considerably higher. Growth is relatively rapid in the first year of life, with fish reaching a size of about 100 mm at age one. Fish reach a length of 300 mm by age five, at which time growth slows. Growth rates of males and females, and of open coast and estuarine populations, appear similar. No growth studies have been undertaken on the west coast of the North Island, but large parore (about 600 mm) are sometimes taken in harbour set-nets as bycatch.

Parore reach sexual maturity at a length of 280 mm and spawning takes place in late spring to early summer (Morrison 1990). Larvae are neustonic, occurring near the ocean's surface, often in association with drifting material such as seaweed clumps.

Juveniles enter estuaries in January at a length of about 11 mm. They are initially found on seagrass meadows and beds of Neptune's Necklace (*Hormosira banksii*) on shallow reefs, but after 3–4 months move down the estuary to other habitats e.g., brown kelp beds. At approximately one year old, they move out to coastal reefs in the immediate vicinity of estuary mouths and over the following 2–3 years move to reef systems further off- and along-shore (Morrison 1990).

Parore are important herbivores in coastal systems and may play a major role in structuring algal assemblages (Morrison 1990). Juvenile parore have been found in the stomachs of kahawai and John dory.

3. STOCKS AND AREAS

There is insufficient biological information available on this species to indicate the existence of separate stocks around New Zealand. However, reliance on localized nursery areas suggests that more than one biological stock may exist.

4. STOCK ASSESSMENT

There has been no scientific assessment of the maximum sustainable yield for parore stocks.

5. STATUS OF THE STOCK

There is no fishery independent information to determine the stock status of parore. Biomass estimates cannot be determined for this species with existing data. Estimates of current and reference biomass are not available. It is not known if recent catch levels or TACs are sustainable. The status of PAR 1, 2 and 9 relative to B_{MSY} is unknown.

PAUA (PAU)

(Haliotis iris, Haliotis australis)

1. INTRODUCTION

Specific Working Group reports are given separately for PAU 2, PAU 3, PAU 4, PAU 5A, PAU 5B, PAU 5D and PAU 7. The TACC for PAU 1, PAU 6 and PAU 10 is 1.93 t, 1 t and 1 t respectively. Commercial landings for PAU 10 since 1983 have been 0 t.

1.1 Commercial fisheries

The commercial fishery for paua dates from the mid-1940s. In the early years of this commercial fishery the meat was generally discarded and only the shell was marketed, however by the late 1950s both meat and shell were being sold. Since the 1986–87 fishing season, the eight Quota Management Areas have been managed with an individual transferable quota system and a total allowable catch (TAC) that is made up of total allowed commercial catch (TACC), recreational and customary catch and other sources of mortality.

Fishers gather paua by hand while free diving (use of underwater breathing apparatus is not permitted). Most of the catch is from the Wairarapa coast southwards: the major fishing areas are in the South Island, Marlborough (PAU 7), Stewart Island (PAU 5A, 5B and 5D) and the Chatham Islands (PAU 4). Virtually the entire commercial fishery is for the black-foot paua, *Haliotis iris*, with a minimum legal size for harvesting of 125 mm shell length. The yellow-foot paua, *H. australis* is less abundant than *H. iris* and is caught only in small quantities; it has a minimum legal size of 80 mm. Catch statistics include both *H. iris* and *H. australis*.

Up until the 2002 fishing year, catch was reported by general statistical areas, however from 2002 onwards, a more finely scaled system of paua specific statistical areas were put in place throughout each QMA (refer to the QMA specific Working Group reports). Figure 1 shows the historical landings for the main PAU stocks. On 1 October 1995 PAU 5 was divided into three separate QMAs: PAU 5A, PAU 5B and PAU 5D.

PAUA (PAU)

Figure 1: Historic landings for the major paua QMAs from 1983–84 to 1995–96 (top) and from 1996–97 to 2016–17 (lower).

Landings for PAU 1, PAU 6, PAU 10 and PAU 5 (prior to 1995) are shown in Table 1. For information on landings specific to other paua QMAs refer to the specific Working Group reports.

* FSU data

1.2 Recreational fisheries

There is a large recreational fishery for paua. Estimated catches from telephone and diary surveys of recreational fishers (Teirney et al 1997, Bradford 1998, Boyd & Reilly 2004, Boyd et al 2004) are shown in Table 2a.

Table 2a: Estimated annual harvest of paua (t) by recreational fishers from telephone-diary surveys*.

Fishstock	PAU 1	PAU 2	PAU 3	PAU 5	PAU5A	PAU5B	PAU 5D	PAU 6	PAU 7
1991–92	-	-	35–60	50–80	-	-	-	-	-
1992–93	-	37–89	-	-	-	-	-	0–1	2–7
1993–94	29–32	-	-	-	-	-	-	-	-
1995–96	10–20	45–65	-	20–35	-	-	-	-	-
1996–97	-	-	-	N/A	-	-	22.5	-	-
1999–00	40–78	224–606	26–46	36–70	-	-	26–50	2–14	8–23
2000–01	16–37	152–248	31–61	70–121	-	-	43–79	0–3	4–11

*1991–1995 Regional telephone/diary estimates, 1995/96, 1999/00 and 2000/01 National Marine Recreational Fishing Surveys.

The harvest estimates provided by telephone-diary surveys between 1993 and 2001 are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. In response to these problems and the cost and scale challenges associated with onsite methods, a National Panel Survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in standardised phone interviews. Harvest estimates for paua are given in Table 2b (from Wynne-Jones et al 2014, using mean weights from Hartill & Davey 2015).

Table 2b: Recreational harvest estimates for paua stocks from the national panel survey in 2011–12 (Wynne-Jones et al 2014). Mean fish weights were obtained from boat ramp surveys (Hartill & Davey 2015).

Stock	Fishers	Events	Number of paua	Total weight (t)	CV
PAU 1	39	63	43 480	12.16	0.27
PAU 2	158	378	286 182	81.85	0.15
PAU 3	35	67	60 717	16.98	0.31
PAU 5A	2	3	1 487	0.42	0.76
PAU 5B	5	5	2 945	0.82	0.50
PAU 5D	41	84	80 290	22.45	0.30
PAU 7	19	41	50 534	14.13	0.34
PAU total	299	641	525 635	148.82	0.11

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

1.3 Customary fisheries

There is an important customary use of paua by Maori for food, and the shells have been used extensively for decorations and fishing devices. Limited data is available for reported customary landings in PAU 3; however no information is available for current levels of customary take for any other paua QMA. Kaitiaki are now in place in many areas and estimates of customary harvest can be expected in the future.

1.4 Illegal catch

Current levels of illegal harvests are not known. In the past, annual estimates of illegal harvest for some Fishstocks were provided by MFish Compliance based on seizures. In the current paua stock assessments, nominal illegal catches are used.

1.5 Other sources of mortality

Paua may die from wounds caused by removal desiccation or osmotic and temperature stress if they are brought to the surface. Sub-legal paua may be subject to handling mortality by the fishery if they are removed from the substrate to be measured. Further mortality may result indirectly from being returned to unsuitable habitat or being lost to predators or bacterial infection. Gerring (2003) observed paua (from PAU 7) with a range of wounds in the laboratory and found that only a deep cut in the foot caused significant mortality (40% over 70 days). In the field this injury reduced the ability of paua to right themselves and clamp securely onto the reef, and consequently made them more vulnerable to predators. The tool generally used by divers in PAU 7 is a custom made stainless steel knife with a rounded tip and no sharp edges. This design makes cutting the paua very unlikely (although abrasions and shell damage may occur). Gerring (2003) estimated that in PAU 7, 37% of paua removed from the reef by commercial divers were undersize and were returned to the reef. His estimate of incidental mortality associated with fishing in PAU 7 was 0.3% of the landed catch. Incidental fishing mortality may be higher in areas where other types of tools and fishing practices are used. Mortality may increase if paua are kept out of the water for a prolonged period or returned onto sand. To date, the stock assessments developed for paua have assumed that there is no mortality associated with capture of undersize animals.

2. BIOLOGY

Paua are herbivores which can form large aggregations on reefs in shallow subtidal coastal habitats. Movement is over a sufficiently small spatial scale that the species may be considered sedentary. Paua are broadcast spawners and spawning is thought to be annual. Habitat related factors are an important source of variation in the post-settlement survival of paua. Growth, morphometrics, and recruitment can vary over short distances and may be influenced by factors such as wave exposure, habitat structure, availability of food and population density. A summary of generic estimates for biological parameters for paua are presented in Table 3. Parameters specific to individual paua QMAs are reported in the specific Working Group reports.

Table 3: Estimates of biological parameters for paua (*H. iris*).

Fishstock	Estimate	Source
1. Natural mortality (M)		
All	0.02–0.25	Sainsbury (1982)
2. $\text{Weight} = a (\text{length})^b$ (weight in kg, shell length in mm)		
$a = 2.99\text{E}^{-08}$	$b = 3.303$	Schiel & Breen (1991)

3. STOCKS AND AREAS

Using both mitochondrial and microsatellite markers Will & Gemmell (2008) found high levels of genetic variation within samples of *H. Iris* taken from 25 locations spread throughout New Zealand. They also found two patterns of weak but significant population genetic structure. Firstly, *H. iris* individuals collected from the Chatham Islands were found to be genetically distinct from those collected from coastal sites around the North and South Islands. Secondly a genetic discontinuity was found loosely associated with the Cook Strait region. Genetic discontinuities within the Cook Strait region have previously been identified in sea stars, mussels, limpets, and chitons and are possibly related to contemporary and/or past oceanographic and geological conditions of the region. This split may have some implications for management of the paua stocks, with populations on the south of the North Island, and the north of the South Island potentially warranting management as separate entities; a status they already receive under the zonation of the current fisheries regions, PAU 2 in the North Island, and PAU 7 on the South Island.

4. STOCK ASSESSMENT

The dates of the most recent survey or stock assessment for each QMA are listed in Table 4.

Table 4: Recent survey and stock assessment information for each paua QMA

QMA	Type of survey or assessment	Date	Comments
PAU 1	No surveys or assessments have been undertaken		
PAU 2	Relative abundance estimate using standardised CPUE index based on commercial catch	2014	Standardised CPUE showed slight oscillation without trend between 1992 and 2001 and has remained flat from 2002 until 2014.
PAU 3	Quantitative assessment using a Bayesian length based model	2013	For the 2013 stock assessment nine model runs were conducted. The Shellfish Working Group agreed on a base case model which estimated M within the model but fixed the growth parameters as providing a reliable estimate of the status of the stocks in PAU 3 with the caveat that the model most likely underestimated uncertainty in growth but adequately estimated uncertainty in natural mortality. The status of the stock was estimated to be 52% B_0

PAUA (PAU)

Table 4 [Continued]

PAU 4	CPUE Standardisation	2016	In February 2010 the Shellfish Working Group (SFWG) agreed that, due to the lack of data of adequate quality to use in the Bayesian length-based model, a stock assessment for PAU 4 using this model was not appropriate. In 2016 an analysis of the last 14 years of CPUE data was done. This report showed a potential decline in the fishery since the early 2000s, however the poor data quality is causing considerable uncertainty about the real trend in the fishery.
PAU 5A	Quantitative assessment using a Bayesian length based model	2014	The 2014 stock assessment was conducted over two subareas of the QMA. The SFWG was satisfied that the stock assessment for both the Southern and Northern areas was reliable based on the available data. The status of the stocks was estimated to be 41% B_0 for the Southern area and 47% B_0 for the Northern area
PAU 5B	Quantitative assessment using a Bayesian length based model	2018	The 2018 Plenary accepted this assessment as best scientific information. The status of the stock was estimated to be 47% B_0 .
PAU 5D	Quantitative assessment using a Bayesian length based model	2016	The reference case model estimated that the unfished spawning stock biomass (B_0) was about 2457 t (2270 – 2672 t) and the spawning stock population in 2016 (B_{2016}) was about 35% (28–43%) of B_0 . The model projection made for three years assuming current catch levels (which includes commercial catch at and using recruitment re-sampled from the recent model estimates, suggested that the spawning stock abundance will increase to about 38% (28–52%) B_0 over the next three years. The projection also indicated that the probability of the spawning stock biomass being above the target (40% B_0) will increase from about 14% in 2016 to 40% by 2019.
PAU 6	Biomass estimate	1996	This fishery has a TACC of 1 t
PAU 7	Quantitative assessment using a Bayesian length based model	2015	The SFWG agreed that the stock assessment was reliable based on the available data. Currently, spawning stock biomass is estimated to be 18% B_0 and is about as likely as not to be below the soft limit, with fishing intensity very likely to be above the overfishing threshold.
PAU 10	No surveys or assessments have been undertaken		

4.1 Estimates of fishery parameters and abundance

For further information on fishery parameters and abundance specific to each paua QMA refer to the specific Working Group report.

In 2014 standardised CPUE indices were constructed to assess relative abundance in PAU 2. In QMAs where quantitative stock assessments have been undertaken, standardised CPUE is also used as input data for the Bayesian length-based stock assessment model. There is however a large amount of literature on abalone which suggests that any apparent stability in CPUE should be interpreted with caution and CPUE may not be proportional to abundance as it is possible to maintain high catch rates despite a falling biomass. This occurs because paua tend to aggregate and, in order to maximise their

catch rates, divers move from areas that have been depleted of paua, to areas with higher density. The consequence of this fishing behaviour is that overall abundance is decreasing while CPUE is remaining stable. This process of hyperstability is believed to be of less concern in PAU 3, PAU 5D and PAU 7 because fishing in these QMAs is consistent across all fishable areas.

In PAU 4, 5A, 5B, 5D and 7 the relative abundance of paua has also been estimated from independent research diver surveys (RDS). In PAU 7, seven surveys have been completed over a number of years but only two surveys have been conducted in PAU 4. In 2009 and 2010 several reviews were conducted (Cordue (2009) and Haist V (2010 MPI .FRR) to assess; i) the reliability of the research diver survey index as a proxy for abundance; and ii) whether the RDS data, when used in the paua stock assessment models, results in model outputs that do not adequately reflect the status of the stocks. The reviews concluded that:

- Due to inappropriate survey design the RDS data appear to be of very limited use for constructing relative abundance indices.
- There was clear non-linearity in the RDS index, the form of which is unclear and could be potentially complex.
- CVs of RDS index 'year' effects are likely to be underestimated, especially at low densities.
- Different abundance trends among strata reduces the reliability of RDS indices, and the CVs are likely not to be informative about this.
- It is unlikely that the assessment model can determine the true non-linearity of the RDS index-abundance relationship because of the high variability in the RDS indices.
- The non-linearity observed in the RDS indices is likely to be more extreme at low densities, so the RDSI is likely to mask trends when it is most critical to observe them.
- Existing RDS data is likely to be most useful at the research stratum level.

4.2 Biomass estimates

Biomass was estimated for PAU 6 in 1996 (McShane et al 1996). However the survey area was only from Kahurangi Point to the Heaphy River.

Biomass has been estimated, as part of the stock assessments, for PAU 4, 5A, 5B, 5D and 7 (Table 4). For further information on biomass estimates specific to each paua QMA refer to the specific Working Group report.

4.3 Yield Estimates and Projections

Yield estimates and projections are estimated as part of the stock assessment process. Both are available for PAU 3, PAU 5A, PAU 5B, PAU 5D and PAU 7. For further information on yield estimates and projections specific to each paua QMA refer to the specific Working Group report.

4.4 Other factors

In the last few years the commercial fishery have been implementing voluntary management actions in the main QMAs. These management actions include raising the minimum harvest size and subdividing QMAs into smaller management areas and capping catch in the different areas and in some QMAs, not catching the full Annual Catch Entitlement (ACE) in a particular fishing year.

5. ENVIRONMENTAL AND ECOSYSTEM CONSIDERATIONS

5.1 Ecosystem role

Paua are eaten by a range of predators, and smaller paua are generally more vulnerable to predation. Smaller paua are consumed by blue cod (Carbines & Beentjes 2003), snapper (Francis 2003), banded wrasse (Russell 1983), spotties (McCardle 1983), triplefins (McCardle 1983) and octopus (Andrew & Naylor 2003). Large paua are generally well protected by their strong shells, but are still vulnerable to rock lobsters (McCardle 1983), the large predatory starfishes *Astrostele scabra* and *Coscinasterias muricata* (Andrew & Naylor 2003). Large paua are also vulnerable to predation by eagle rays (McCardle 1983), but Ayling & Cox (1982) suggested that eagle rays feed almost exclusively on Cook's turban. There are no known predators that feed exclusively on paua.

Paua feed preferentially on drift algae but at high densities they also feed by grazing attached algae. They are not generally considered to have a large structural impact upon algal communities but at high densities they may reduce the abundance of algae. There are no recognised interactions with paua abundance and the abundance or distribution of other species, with the exception of kina which, at very high densities, appear to exclude paua (Andrew et al 2000). Research at D'Urville Island and on Wellington's south coast suggests that there is some negative association between paua and kina (Andrew & MacDiarmid 1999).

5.2 Fish and invertebrate bycatch

Because paua are harvested by hand gathering, incidental bycatch is limited to epibiota attached to, or within the shell. The most common epibiont on paua shell is non-geniculate coralline algae, which, along with most other plants and animals which settle and grow on the shell, such as barnacles, oysters, sponges, bryozoans, and algae, appears to have general habitat requirements (i.e. these organisms are not restricted to the shells of paua). Several boring and spiral-shelled polychaete worms are commonly found in and on the shells of paua. Most of these are found on several shellfish species, although within New Zealand's shellfish, the onuphid polychaete *Brevibrachium maculatum* has been found only in paua shell Handley, S. (2004). This species; however, has been reported to burrow into limestone, or attach its tube to the holdfasts of algae (Read 2004). It is also not uncommon for paua harvesters to collect predators of paua (mainly large predatory starfish) while fishing and to effectively remove these from the ecosystem. The levels of these removals are unlikely to have a significant effect on starfish populations (nor, in fact, on the mortality of paua caused by predation).

5.3 Incidental catch (seabirds, mammals, and protected fish)

There is no known bycatch of threatened, endangered, or protected species associated with the hand gathering of paua.

5.4 Benthic interactions

The environmental impact of paua harvesting is likely to be minimal because paua are selectively hand gathered by free divers. Habitat contact by divers at the time of harvest is limited to the area of paua foot attachment, and paua are usually removed with a blunt tool to minimise damage to the flesh. The diver's body is also seldom in full contact with the benthos. Vessels anchoring during or after fishing have the potential to cause damage to the reef depending on the type of diving operation (in many cases, vessels do not anchor during fishing). Damage from anchoring is likely to be greater in areas with fragile species such as corals than it is on shallow temperate rocky reefs. Corals are relatively abundant at shallow depths within Fiordland, but there are seven areas within the sounds with significant populations of fragile species where anchoring is prohibited.

5.5 Other considerations

5.5.1 Genetic effects

Fishing, environmental changes, including those caused by climate change or pollution, could alter the genetic composition or diversity of a species and there is some evidence to suggest that genetic changes may occur in response to fishing of abalones. Miller et al (2009) suggested that, in *Haliotis rubra* in Tasmania, localised depletion will lead to reduced local reproductive output which may, in turn, lead to an increase in genetic diversity because migrant larval recruitment will contribute more to total larval recruitment. Enhancement of paua stocks with artificially-reared juveniles has the potential to lead to genetic effects if inappropriate broodstocks are used.

5.5.2 Biosecurity issues

Undaria pinnatifida is a highly invasive opportunistic kelp which spreads mainly via fouling on boat hulls. It can form dense stands underwater, potentially resulting in competition for light and space which may lead to the exclusion or displacement of native plant and animal species. *Undaria* may be transported on the hulls of paua dive tenders to unaffected areas. Bluff Harbour, for example, supports a large population of *Undaria*, and is one of the main ports of departure for fishing vessels harvesting paua in Fiordland, which appears to be devoid of *Undaria* (R. Naylor, personal observation). In 2010, a small population of *Undaria* was found in Sunday Cove in Breaksea Sound, and attempts to eradicate it appear to have been successful (see <http://www.biosecurity.govt.nz/pests/undaria>).

5.5.3 Kaikoura Earthquake

Research is underway to investigate the influence of the November 2016 Kaikoura earthquake on paua stocks in the area of the Kaikoura coastline that is currently closed to harvest.

5.5.4 Marine heatwave

The effects of warming trends and ocean acidification trends, and the marine heatwave in NZ of up to 6°C higher temperatures experienced over summer 2017-18 have not been explored.

6. STATUS OF THE STOCKS

The status of paua stocks PAU 2, PAU 3, PAU 4, PAU 5A, PAU 5B, PAU 5D and PAU 7 are given in the relevant Working Group reports.

PAUA (PAU 2) – Wairarapa / Wellington / Taranaki

(Haliotis iris)
Pāua

1. FISHERY SUMMARY

PAU 2 was introduced into the Quota Management System in 1986–87 with a TACC of 100 t. As a result of appeals to the Quota Appeal Authority, the TACC was increased to 121.19 t in 1989 and has remained unchanged to the current fishing year (Table 1). There is no TAC for this QMA: before the Fisheries Act (1996) a TAC was not required. When changes have been made to a TACC after 1996, stocks have been assigned a TAC.

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 2 since introduction to the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1989	-	-	-	-	100
1989–present	-	-	-	-	121.19

1.1 Commercial fisheries

The fishing year runs from 1 October through to 30 September. Most of the commercial catch comes from the Wairarapa and Wellington South coasts between Castle Point and Turakirae Head. The western area between Turakirae Head and the Waikanae River is closed to commercial fishing.

On 1 October 2001 it became mandatory to report catch and effort on PCELRs using the fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme (Figure 1).

1.2 Recreational fisheries

The most recent recreational fishery survey “The National Panel Survey of Marine Recreational Fishers 2011–12: Harvest Estimates (2014)”, estimated about 80 t of paua were harvested by recreational fishers in PAU 2 in 2011–12.

Because paua around Taranaki are naturally small and never reach the minimum legal size (MLS) of 125 mm, a new MLS of 85 mm was introduced for recreational fishers from 1 October 2009. The new length was on a trial basis for five years and now applies between the Awakino and Wanganui rivers.

PAUA (PAU 2)

Figure 1: Map of fine scale statistical reporting areas for PAU 2.

Landings for PAU 2 are shown in Table 2.

Table 2: TACC and reported landings (t) of paua in PAU 2 from 1983–84 to present.

Year	Landings	TACC

2016–17	123.69	121.19

* FSU data.

1.3 Customary fisheries

For further information on customary fisheries refer to the introductory PAU Working Group Report.

1.4 Illegal catch

It is widely believed that the level of illegal harvesting is high around Wellington and on the Wairarapa coast. For further information on illegal catch refer to the introductory PAU Working Group Report.

Figure 2: Historical landings and TACC for PAU 2 from 1983–84 to present. QMS data from 1986–present.

1.5 Other sources of mortality

For further information on other sources of mortality refer to the introductory PAU Working Group Report.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Working Group Report. A summary of published estimates of biological parameters for PAU 2 is presented in Table 3.

Table 3: Estimates of biological parameters (*H. iris*)

Area		Estimate	Source
<u>1. Size at maturity (shell length)</u>			
Wellington	50% mature	71.7 mm	Naylor et al (2006)
Taranaki	50% mature	58.9 mm	Naylor & Andrew (2000)
<u>2. Fecundity = a (length)^b (eggs, shell length in mm)</u>			
Taranaki	a = 43.98	b = 2.07	Naylor & Andrew (2000)
<u>3. Exponential growth parameters (both sexes combined)</u>			
Wellington	g ₅₀	30.58 mm	Naylor et al (2006)
	g ₁₀₀	14.8 mm	
Taranaki	G ₂₅	18.4 mm	Naylor & Andrew (2000)
	G ₇₅	2.8 mm	

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Working Group Report.

4. RELATIVE ABUNDANCE INDEX

A standardised CPUE index based on commercial catch was constructed covering the 1990 to 2014 fishing years (McKenzie 2015). Two separate indexes were estimated, the first was estimated from CELR data for the fishing years 1989–90 to 2001–02, and the second was estimated from PCELR data for the fishing years 2002–03 to 2013–14. FSU data covering the period from 1983 to 1988 was not used in the standardisation due to problems with this data including: 1) a high proportion of missing values for the vessel field; 2) ambiguity and inaccuracies in what is recorded for the important fishing duration field and 3) low coverage of the annual catch.

There was little evidence of serial depletion over the past 13 years (Figure 3).

Figure 3: Annual estimated catch by fine-scale statistical area in PAU 2 for fishing years 2002–2014. The size of the circle is proportional to the catch. The red dashed lines delineate different regions.

The CPUE standardisations used the following criteria:

- To restrict the catch-effort records to those from the old statistical areas 014, 015, 016 (CELR data) and zones P201–P236 (PCELR data). These areas contain most of the commercial catch.
- For the CELR data standardisation to use a subset of the groomed data for which the recorded duration would be less ambiguous. The criteria to be used to subset the data are: (i) just one diver, or (ii) fishing duration ≥ 6 hours and number of divers ≥ 2 . For this subsetted data set, offer both number of divers and duration (as a polynomial) to the model.
- Do a sensitivity CELR data standardisation where the fishing duration cut-off is 4 hours: (i) just one diver, or (ii) fishing duration ≥ 4 hours and number of divers ≥ 2 .
- To use Fisher Identification Number (FIN) in standardisation procedures instead of vessel.
- Not to put in a year and area interaction in the standardisations (which would be used in a single area assessment), but to explore area differences in catch rates by doing separate standardisations where a year and area interaction is forced in at the start. For the CELR data the smallest possible area sub-divisions are 014, 015, and 016. For the PCELR data a close, but more natural division of the areas is South, East, and North (Figure 3), where the large East area can be broken up further based on the strata used for length-frequencies.

4.1 CELR: the standardisation

CPUE was defined as daily catch. Year was forced into the model at the start and other predictor variables offered to the model were FIN, Statistical Area (014, 015, 016), month, fishing duration (as a cubic polynomial), number of divers, and a month:area interaction. Following previous standardisations, no interaction of fishing year with area was entered into the model, however, a separate standardisation is also done where a year:area interaction is forced in at the start.

The model explained 77% of the variability in CPUE with fishing duration (70%) explaining most of this followed by FIN (3%). The effects appear plausible and the model diagnostics were good. The standardised index declines for the first four years, then increases, with a drop in the last year (Table 4, Figure 4).

Table 4: Standardised CELR index, lower and upper 95% confidence intervals, and CV.

Year	index	lower.CI	upper.CI	CV
1990	1.01	0.88	1.17	0.07
1991	0.94	0.81	1.07	0.07
1992	0.89	0.78	1.02	0.07
1993	0.89	0.78	1.01	0.06
1994	0.87	0.76	0.99	0.06
1995	0.91	0.80	1.03	0.06
1996	0.99	0.87	1.12	0.06
1997	0.98	0.86	1.13	0.07
1998	1.08	0.92	1.27	0.08
1999	1.19	1.02	1.39	0.08
2000	1.21	1.03	1.42	0.08
2001	1.13	0.97	1.31	0.08

Figure 4: The standardised CPUE index with 95% confidence intervals. The unstandardised geometric CPUE is calculated as daily catch divided by daily fishing duration.

As a sensitivity to the filtering criteria for the subsetted data set (in which the fishing duration field should be less ambiguous), another standardisation was done in which when the number of divers was ≥ 2 then the fishing duration has to be ≥ 4 hours (instead of 6 hours). The resulting index is very similar to that when 6 hours is used (Figure 5).

Figure 5: Sensitivity using four hours or more (for two or more divers).

4.2 PCELR: the standardisation

For the standardisation model CPUE (the dependent variable) was modelled as log of the diver catch with a normal error distribution. Fishing year was forced into the model at the start. Variables offered to the model were month, diver key, FIN, statistical area, duration (third degree polynomial), and diving condition. Following previous standardisations, no interaction of fishing year with area was entered into the model however, a separate standardisation is also done where a year:area interaction is forced in at the start.

Except for month, all variables were accepted into the model, which explained 73% of the variability in CPUE. Most of the variability was explained by duration (56%) and diver (9%). The effects appear plausible and the diagnostics were good. There is an apparent increasing effect for the catch taken after a fishing duration of 10 hours, although for the majority of records fishing duration is less than 10 hours.

The standardised index shows a slow decline from 2002 to 2012 with a slight increase since then (Table 5, Figure 6). As the standardised index shows little contrast since 2002, and there is little growth data available for PAU 2, stock assessment model estimates of biomass would be highly uncertain and not useful for management purposes. Because of this it was decided by the Shellfish Working Group that a full stock assessment should not be undertaken for PAU 2.

Table 5: Standardised index for the PCELR data set, lower and upper 95% confidence intervals and CV.

Year	index	lower.CI	upper.CI	CV
2002	1.13	0.99	1.28	0.06
2003	1.05	0.94	1.16	0.05
2004	1.05	0.95	1.16	0.05
2005	1.01	0.92	1.11	0.05
2006	1.04	0.94	1.15	0.05
2007	0.95	0.86	1.05	0.05
2008	0.94	0.86	1.04	0.05
2009	0.99	0.89	1.10	0.05
2010	0.97	0.88	1.08	0.05
2011	0.95	0.86	1.05	0.05
2012	0.95	0.86	1.05	0.05
2013	1.01	0.90	1.12	0.05
2014	0.98	0.86	1.11	0.07

Figure 6: The standardised CPUE index for the PCELR dataset with 95% confidence intervals. The unstandardised geometric CPUE is calculated as daily catch divided by daily fishing duration.

It should be noted that a large amount of literature on abalone suggests that any apparent stability in CPUE should be interpreted with caution; and CPUE may not be proportional to abundance as it is possible to maintain high catch rates despite a falling biomass. This occurs because paua tend to aggregate and in order to maximise their catch rates divers' move from areas that have been depleted of paua, to areas with higher density. The consequence of this fishing behaviour is that overall abundance is decreasing but CPUE is remaining stable. This may not be such a large problem in PAU 2 because distribution of catch has been consistent for many years and there is little evidence of serial depletion occurring (Figure 3).

5. STATUS OF THE STOCKS

Stock Structure Assumptions

A genetic discontinuity between North Island and South Island paua populations was found approximately around the area of Cook Strait (Will & Gemmell 2008).

- PAU 2 - *Haliotis iris***

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	Standardised CPUE index
Reference Points	Target: 40% B_0 (Default as per HSS) Soft Limit: 20% B_0 (Default as per HSS) Hard Limit: 10% B_0 (Default as per HSS) Overfishing threshold: -
Status in relation to Target	Unknown
Status in relation to Limits	Unlikely (< 40%) to be below the Soft Limit Unlikely (< 40%) to be below the Hard Limit
Status in relation to Overfishing	Unknown: There are no data for recreational or illegal catch and both are likely to be significant.

Historical Stock Status Trajectory and Current Status

Standardised and unstandardized CPUE index for 1990–2001 with 95% confidence intervals. The unstandardised geometric CPUE is calculated as daily catch divided by daily fishing duration.

Standardised and unstandardized CPUE index for 2002–2014 using PCELR data, with 95% confidence intervals. The unstandardised geometric CPUE is calculated as daily catch divided by daily fishing duration.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	From 1989–90 to 2001–02 the standardized CPUE index oscillates without any obvious trend, and from 2002–03 until 2013–14 the index is flat.

Qualifying Comments		
CPUE is not generally considered to be a reliable indicator of the status of paua stocks and may not reflect abundance. A large portion of PAU 2, including the Wellington south coast, is closed to commercial fishing. This means that the CPUE series collected from the commercial catch and effort data are exclusive of this large area and therefore the abundance of paua in the fishery as a whole will not be captured well by the CPUE index.

PAUA (PAU 3) – Canterbury / Kaikoura*(Haliotis iris)*

Pāua

**1. FISHERY SUMMARY****1.1 Commercial fisheries**

PAU 3 was introduced into the Quota Management System in 1986–87 with a TACC of 57 t. As a result of appeals to the Quota Appeal Authority, the TACC was increased to 91.62 t in 1995 and has remained unchanged to the current fishing year (Table 1).

There is no TAC for PAU 3 (Table 1): before the Fisheries Act (1996) a TAC was not required. When changes have been made to a TACC after 1996, stocks have been assigned a TAC. No allowances have been made for customary, recreational or other mortality.

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 3 since introduction to the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1995	-	-	-	-	57
1995–present	-	-	-	-	91.615

The fishing year runs from 1 October through 30 September.

Most of the commercial catch comes from the northern part of the QMA between the northern end of Pegasus Bay and the Clarence River, and from the southern side of Banks Peninsula.

On 1 October 2001 it became mandatory to report catch and effort on Paua Catch Effort Landing Returns (PCELRs) using fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme (Figure 1). Reported landings for PAU 3 are shown in Table 2 and Figure 2.

Since 2001, a redistribution of fishing effort within PAU 3 has been undertaken by the industry as a response to fears that the more accessible northern part of the fishery was being overfished. A voluntary subdivision was agreed by PauaMAC 3 which divided PAU 3 into four management zones (Table 3). A voluntary harvest cap is placed on each management zone and this cap is reviewed annually. Minimum

PAUA (PAU 3)

harvest sizes (MHS) are also agreed for each zone in addition to the legislated Minimum Legal Size (MLS). These are also reviewed annually.

Figure 1: Map of fine scale statistical reporting areas for PAU 3.

Landings for PAU 3 are shown in Table 2.

Table 2: TACC and reported landings (t) of paua in PAU 3 from 1983–84 to present.

**Figure 2: Reported commercial landings and TACC for PAU 3 from 1983–84 to present. QMS data from 1983–present.**

1.2 Recreational fisheries

For further information on recreational fisheries refer to the introductory PAU Working Group Report. The ‘National Panel Survey of Marine Recreational Fishers 2011–12: Harvest Estimates’ estimated that the recreational harvest for PAU 3 was 16.98 ton with a C.V. of 30%. For the purpose of the 2013 stock assessment, the Shellfish Working Group (SFWG) agreed to assume that the recreational catch rose linearly from 5t in 1974 to 17 t in 2013.

1.3 Customary fisheries

Estimates of customary catch for PAU 3 over the period where reliable estimates are available are shown in Table 4. Landings before 2010–11 do not include the area between the Hurunui River and the South Shore (just north of Banks Peninsula), as Tangata Tiaki were not appointed there until November 2009. Many tangata whenua also harvest paua under their recreational allowance and these are not included in records of customary catch.

Table 4: Reported customary landings (t) of paua in PAU 3 from 2000–01 to 2013–14. Landings data before 2010–11 exclude the area between the Hurunui and Pegasus Bay.

Year	Landings (t)
2000–01	1.64
2001–02	5.67
2002–03	3.84
2003–04	5.83
2004–05	1.95
2005–06	1.90
2006–07	4.56
2007–08	5.79
2008–09	8.23
2009–10	6.47
2010–11	7.45
2011–12	4.24
2012–13	12.87
2013–14	7.57

1.4 Illegal catch

For further information on illegal catch refer to the introductory PAU Working Group Report. For the purpose of the 2013 stock assessment, the SFWG agreed to assume that illegal catches rose linearly from 5t in 1974 to 15 t in 2000, and remained at 15 t between 2001 and 2013.

1.5 Other sources of mortality

The Working Group agreed that handling mortality would not be included in the model. For further information on other sources of mortality refer to the introductory PAU Working Group Report.

On 16 November 2016 a 7.8 magnitude earthquake hit the upper east coast of the South Island, uplifting areas of the coast by as much as 4 m. The whole northern part of the PAU 3 fishery (Paua Statistical Areas P301 to P310, Figure 3) were impacted to varying degrees by the earthquake. The earthquake caused direct mortality of a large number of juvenile and adult paua that became exposed to the terrestrial environment with no means of being able to return to the water. More indirect mortality is also expected from the earthquake due to an immediate loss of pre-earthquake paua habitat that now lies above the new post-earthquake high tide mark.

Although the impacts of the seabed uplift on paua populations around Kaikoura will only become clear in the longer term, work was undertaken to evaluate the area utilised by the paua fishery that is now above the post earthquake low-tide mark (Neubauer 2016). The results estimated that the seabed uplift led to a loss of up to 50% of the pre-earthquake fished area in the paua statistical areas P301 to P310. In area 301, the habitat loss was 7 ha, which corresponds to 52% of the fished area. However, this area has contributed relatively little to the commercial catch. In area 302, which has contributed a larger proportion of the PAU 3 commercial catch, the area lost was 43 ha, which corresponds to 43% of the fished area. In other affected areas, the area lost was generally less than 10%. Across PAU 3 statistical areas, a total of 21% of the fished area (24% of catch weight as recorded on PCELR forms), was impacted by uplift (Figure 3).

The immediate loss of area to the fishery, assumed to be good habitat for paua, is only part of the impact that the seabed uplift associated with the Kaikoura earthquake will have on paua populations. Juvenile paua recruit in shallow water, and so the loss of juvenile habitat will have been higher than the loss of adult habitat. This will impact on the number of juvenile paua growing into the fishery over the coming years. This impact will be more difficult to quantify directly, but may affect paua populations and fisheries over a span of multiple years.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Working Group Report. A summary of published estimates of biological parameters for PAU 3 is presented in Table 5.

Table 5: Estimates of biological parameters (*H. iris*) in PAU 3.

	Estimate	Source
1. Natural mortality (<i>M</i>)	0.135 (0.120–0.153)	Median (5–95% range) of posterior distribution for the base case model
2. $\text{Weight} = a(\text{length})^b$ (Weight in g, length in mm shell length)		
All	<div style="display: flex; justify-content: space-around;"> a 2.99×10^{-5} b 3.303 </div>	Schiel & Breen (1991)
3. Size at maturity (shell length)		
	50% maturity at 82 mm (80–84)	Median (5–95% range) of posterior distribution for the base case model
	95% maturity at 102 mm (96–108)	Median (5–95% range) of posterior distribution for the base case model

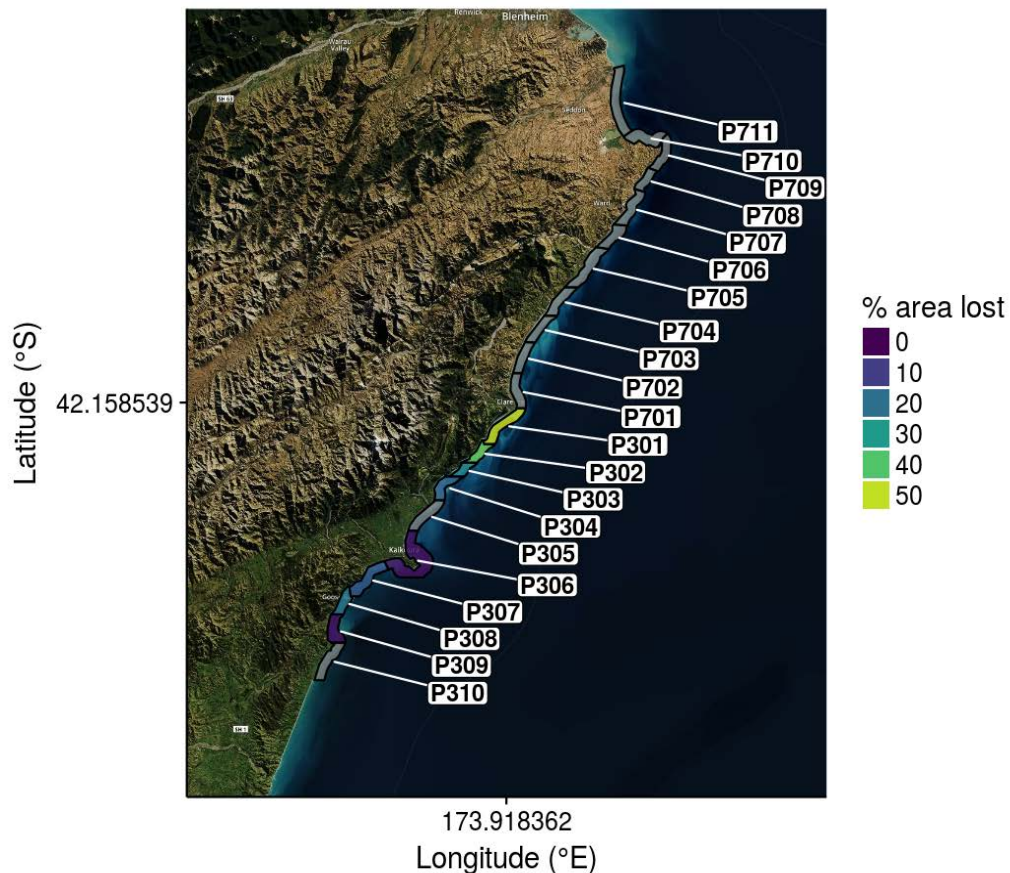

Figure 3: Percent fished area above the post-earthquake low tide mark for statistical areas within the Kaikoura earthquake fishery closure zone. Grey indicates that no post-earthquake elevation data was available.

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Working Group Report.

4. STOCK ASSESSMENT

The stock assessment was implemented using a length-based Bayesian estimation model, with parameter point estimates based on the mode of the joint posterior distribution and uncertainty based on marginal posterior distributions generated from Markov chain-Monte Carlo (MCMC) simulations. The most recent stock assessment was conducted in 2014 for the fishing year ended 30 September 2013. The Shellfish WG determined a set of model runs where growth and natural mortality parameter values were fixed. The parameter values were thought to cover the plausible range of productivity assumptions for the stock. Markov chain-Monte Carlo (MCMC) simulations were conducted on a model agreed to by the SFWG. This particular model (6.1) estimated M within the model (with a lognormal prior with a mean of 0.1) but fixed the growth parameters at the medium value ($g_1=20$ mm, $g_2=6$ mm). On reviewing the results of the MCMC simulations the SFWG chose model 6.1 as the base case. The lack of comprehensive growth and length frequency data for PAU 3 and the lack of contrast in the CPUE series mean's uncertainty in the model outputs is higher than preferred.

4.1 Estimates of fishery parameters and abundance indices

Assumed prior distributions for model parameters are summarized in Table 6.

Table 6: A summary of estimated model parameters, lower bound, upper bound, type of prior, (U, uniform; N, normal; LN = lognormal), mean and C.V. of the prior.

Parameter	Prior	μ	C.V.	Bounds	
				Lower	Upper
$\ln(R0)$	U	–	–	5	50
M (Natural mortality)	LN	0.1	0.35	0.01	0.5
$\ln(q')$ (catchability coefficient of CPUE)	U	–	–	-30	0
$\ln(q')$ (catchability coefficient of PCPUE)	U	–	–	-30	0
L_{50} (Length at 50% maturity)	U	–	–	70	145
L_{95-50} (Length between 50% and 95% maturity)	U	–	–	1	50
D_{50} (Length at 50% selectivity for the commercial catch)	U	–	–	70	145
D_{95-50} (Length between 50% and 95% selectivity the commercial catch)	U	–	–	0.01	50
ϵ (Recruitment deviations)	N	0	0.4	-2.3	2.3

The observational data were:

1. A 1990–2001 standardised CPUE series based on CELR data.
2. A 2002–2012 standardised CPUE series based on PCELR data.
3. A commercial catch sampling length frequency series for 2000, 2002–2012.
4. Maturity at length data

4.1.1 Relative abundance estimates from standardised CPUE analyses

The 2013 stock assessment used two sets of standardised CPUE indices: one based on CELR data covering 1990–2001, and another based on PCELR data covering 2002–2013. For both series, standardised CPUE analyses were carried out using Generalised Linear Models (GLMs). A stepwise procedure was used to select predictor variables, with variables entering the model in the order that gave the maximum decrease in the residual deviance. Predictor variables were accepted into the model only if they explained at least 1% of the deviance.

For both the CELR and PCELR data, the Fisher Identification Number (FIN) was used in the standardisations instead of vessel, because the FIN is associated with a permit holder who may employ a suite of grouped vessels, which implies that there could be linkage in the catch rates among vessels operated under a single FIN.

For the CELR data there is ambiguity in what is recorded for estimated daily fishing duration, and therefore daily fishing duration has not been used in past standardisations as a measure of effort; instead the number of divers has been used. However, there is evidence that the fishing duration for a diver changes over time, and because of this a subset of the data was selected for which the recorded fishing duration was less ambiguous. The criteria used to subset the data were: (i) just one diver or, (ii) fishing duration ≥ 6 hours and number of divers ≥ 2 . This data subset was used for the CELR standardisation, using estimated daily catch and effort measured as either number of divers or fishing duration (both were offered to the standardisation model).

For the PCELR data the unit of catch was diver catch, with effort as diver duration. The diver duration measures the number of hours fished per diver day.

FIN codes were used to select a core group of fishers from the CELR data, with the requirement that there be a minimum of 6 records per year for a minimum of 2 years to qualify for the core fisher group. This retained 84% of the catch over 1990–2001. For the PCELR data the FIN was also used to select a core group of fishers, with the requirement that there be a minimum of 20 records per year for a minimum of 2 years. This retained 84% of the catch over 2002–2013.

For the CELR data, year was forced into the model and other predictor variables offered to the model were FIN, Statistical Area (018, 020, 022), month, fishing duration (as a cubic polynomial), number of divers, and a month:area interaction. Variables accepted into the model were fishing year, month, FIN, and fishing duration. Following previous standardisations, no interaction of fishing year with area was entered into the model as the stock assessment for PAU 3 is a single area model. However, a separate standardisation is also done where a year:area interaction is forced in. Forcing in a year:area interaction

indicates that there are differences in standardised CPUE between the area 018 and the two areas 020 and 022. However, in the years where they differ there are very few records to estimate the year effects for areas 020 and 022.

For the PCELR data, fishing year was forced into the model and variables offered to the model were month, diver key, FIN statistical area, diver duration (third degree polynomial), and diving conditions. All the variables were accepted into the final model.

The standardised CPUE from the CELR data is flat from 1990 to 1994, shows a rise of 20% from 1995 to 1998, then declines for the next three years to 2001 (Figure 4–top). The standardised CPUE from the PCELR data shows a gradual decline of 10% from 2002 to 2013 (Figure 4–bottom).

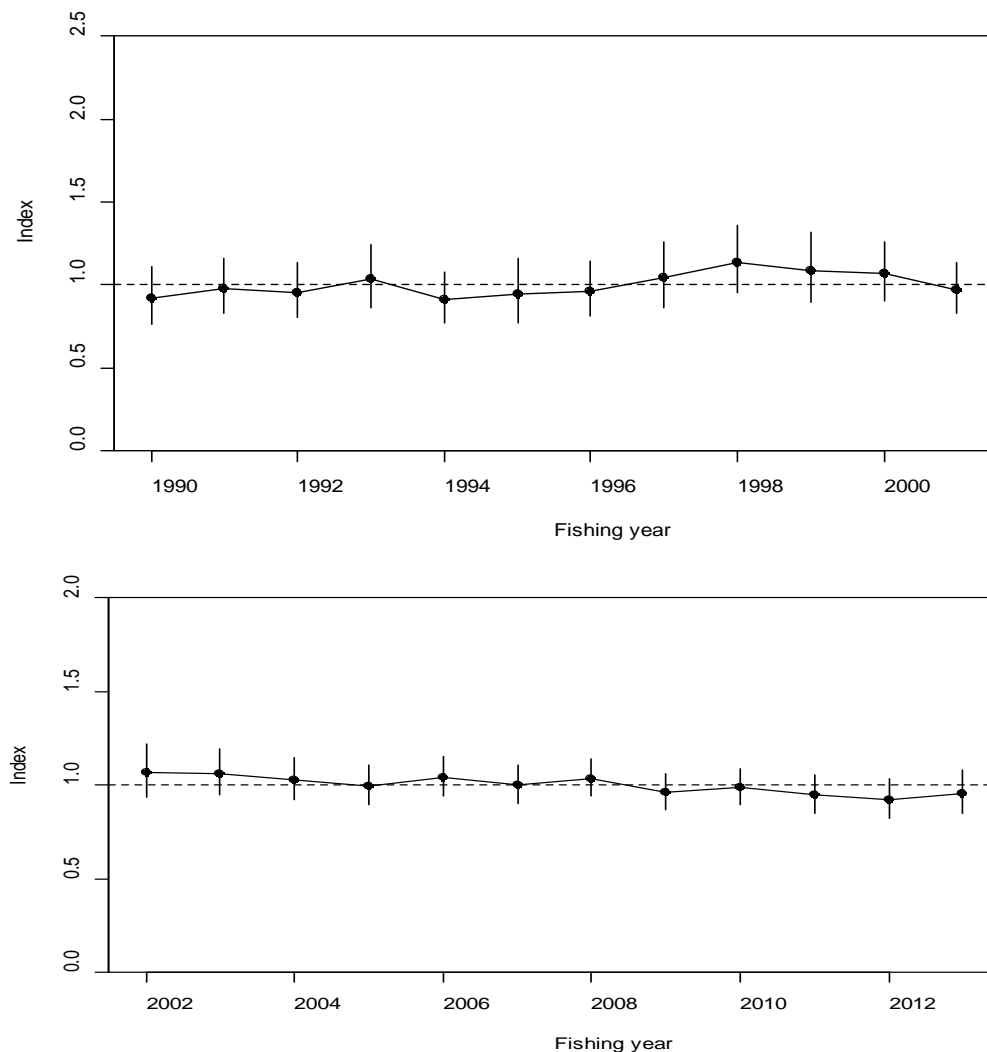

Figure 4: The standardised CPUE indices with 95% confidence intervals for the early CELR/FSU series (top panel) and the recent PCELR series (bottom panel).

4.2 Stock assessment methods

The 2013 PAU 3 stock assessment used the same length-based model as the 2012 PAU 5D assessment (Fu 2013). The model was described by Breen et al (2003). This is the first assessment for PAU 3 using the length based Bayesian model (Fu 2014).

The model structure assumed a single sex population residing in a single homogeneous area, with length classes from 70 mm to 170 mm, in 2 mm bins. Growth is length-based, without reference to age, mediated through a growth transition matrix that describes the probability of transition among length classes at each time step. Paua enter the model following recruitment and are removed by natural mortality and fishing mortality.

PAUA (PAU 3)

The models were run for the years 1965–2013. Catches were collated for 1974–2013, and were assumed to increase linearly between 1965 and 1973 from 0 to the 1974 catch level. Catches included commercial, recreational, customary, and illegal catch, and all catches occurred at the same time step.

Recruitment was assumed to take place at the beginning of the annual cycle, and length at recruitment was defined by a uniform distribution with a range between 70 and 80 mm. The stock-recruitment relationship is unknown for paua. A relationship may exist on small geographical scales, but not be apparent when large geographical scales are modelled (Breen et al 2003). However, the Shellfish Working Group agreed to use a Beverton-Holt stock-recruitment relationship with steepness (h) of 0.75 for this assessment.

Maturity is not required in the population partition but is necessary for estimating spawning biomass. The model estimated proportions mature from length-at-maturity data. Growth and natural mortalities were also estimated within the model. The model estimated the commercial fishing selectivity, assumed to follow a logistic curve and asymptote at 1.

The growth data available to the PAU 3 assessment were collected from several sites in Banks Peninsula. Because most of the paua measured in this experiment were stunted, incorporating these data in the assessment would under-estimate the growth for the whole stock. There were also some growth measurements from an experiment conducted in Cape Campbell (within PAU 7) which is close to the northern boundary of PAU 3, but the sample size is too small to be useful. Therefore the growth parameters were fixed in this assessment.

The growth parameter were fixed at low ($g_1=15$ mm, $g_2=4.5$ mm), median ($g_1=20$ mm, $g_2=6$ mm), and high ($g_1=25$ mm, $g_2=7.5$ mm) values. The median values were based on the estimates of growth using the tag-recapture data from Cape Campbell (Fu 2014). The low and high values were loosely based on the range of growth estimates from assessments of other paua stocks. For each fixed value of the growth parameters, natural mortality was fixed at three levels, 0.1, 0.15, and 0.2. These values were considered to have covered the plausible range of natural mortality for paua. In total nine model runs were carried out. The growth and natural mortality parameter values aimed to evaluate the sensitivity of model results to key productivity assumptions and to estimate uncertainty in stock status. Each model run was considered an equally likely scenario. The models were fitted to the data with parameters estimated at the mode of their joint posterior distribution (MPD).

Markov chain-Monte Carlo (MCMC) simulations were conducted on a model agreed to by the SFWG in order to obtain a large set of samples from the joint posterior distribution. This particular model (6.1) estimated M within the model (with a lognormal prior with a mean of 0.1) but fixed the growth parameters at the medium value ($g_1=20$ mm, $g_2=6$ mm).

The assessment calculates the following quantities from the posterior distributions: the equilibrium spawning stock biomass with recruitment equal to the average recruitment over the period for which recruitment deviations were estimated (B_0); and the mid-season spawning and recruited biomass for 2013 (B_{2013} and B_{2013}^r) and for the projection period (B_{proj} and B_{proj}^r).

This assessment also reports the following fishery indicators:

- $B\% B_0$ Current or projected spawning biomass as a percentage of B_0
- $B\% B_{msy}$ Current or projected spawning biomass as a percentage of B_{msy}
- $\Pr(B_{proj} > B_{msy})$ Probability that projected spawning biomass is greater than B_{msy}
- $\Pr(B_{proj} > B_{2013})$ Probability that projected spawning biomass is greater than $B_{current}$
- $B\% B_0^r$ Current or projected recruited biomass as a percentage of B_0^r
- $B\% B_{msy}^r$ Current or projected recruited biomass as a percentage of B_{msy}^r

- $\Pr(B_{proj} > B_{msy}^r)$ Probability that projected recruit-sized biomass is greater than B_{msy}^r
- $\Pr(B_{proj} > B_{2013}^r)$ Probability that projected recruit-sized biomass is greater than B_{2013}^r
- $\Pr(B_{proj} > 40\% B_0)$ Probability that projected spawning biomass is greater than 40% B_0
- $\Pr(B_{proj} < 20\% B_0)$ Probability that projected spawning biomass is less than 20% B_0
- $\Pr(B_{proj} < 10\% B_0)$ Probability that projected spawning biomass is less than 10% B_0
- $\Pr(U_{proj} > U_{40\% B_0})$ Probability that projected exploitation rate is greater than $U_{40\% B_0}$

4.3 Stock assessment results

For the nine model runs in which growth and natural mortality were fixed B_0 ranged from 1500 t to 2900 t, and $B_{current}$ ranged from 21% to 66% of B_0 (Table 7). All model runs showed an overall decreasing trend in spawning stock biomass but this trend has become slower in recent years (Figure 5). In general, models with higher values for M and growth had higher estimates of initial and current biomass, and models with lower M and growth had lower estimates of biomass.

When M was fixed at 0.1, the models fitted the CSLF and CPUE data poorly. Model fits improved markedly when M was increased to 0.15 or 0.20. The SFWG believed that 0.15 is probably more credible than 0.2 for the natural mortality of paua. Model fits and likelihood function values did not provide a clear distinction among low, median, or high growth values. Estimates of stock depletion levels were sensitive to the assumed value of the growth parameters.

For model (6.1), the posterior of M had a median of 0.14 with a 90% credible interval between 0.12 and 0.15. The posterior distributions of spawning stock biomass showed a gradual declining trend (Figure 6), estimated B_0 was about 2670 t (2470–2960t) and $B_{current}$ was about 52% (45–60%) of B_0 (Table 8). The SFWG agreed for this model to be adopted as the base case model, but noted that the model underestimates uncertainty in stock biomass and status because of uncertainty in growth.

The estimates of recruitment deviations showed a period of relatively low recruitment between 1980 the 1990 and recruitment in recent years (after 2002) has been above the long term average. Exploitation rates showed a gradual upward trend since the 2000s, and the estimated exploitation rate in 2013 was about 0.16 (0.09–0.14) (Table 8).

Model projections, assuming current catch levels and using recruitments re-sampled from the recent model estimates, suggested that the spawning stock abundance will slightly decrease to about 51% (41–63) of B_0 over the next three years (Table 9). The projections indicated that the probability of the spawning stock biomass being above the target (40% B_0) over the next three years is close to 100%.

Table 7: MPD estimates of B_0 , B_{2013} , and U_{2013} for models 3.1–3.3, 4.1–4.3, and 5.1–5.3.

Model	M	g_1	g_2	B_0	B_{2013}	B_{2013}/B_0	U_{2013}

Figure 5 [Continued]: Estimates of spawning stock biomass as a ratio of B_0 (bottom panel) for MPD models 3.1, 3.2, 3.3, 4.1, 4.2, 4.3, 5.1, 5.2, and 5.3.

Figure 6: Posterior distributions of spawning stock biomass (top panel) and spawning stock biomass as a percentage of virgin level (bottom panel) from MCMC 6.1 (including projections). The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

4.4 Other factors

The assessment used CPUE as an index of abundance. The assumption that CPUE indexes abundance is questionable. The literature on abalone suggests that CPUE is difficult to use in abalone stock assessments because of serial depletion. This can happen when fishers deplete unfished or lightly fished beds and maintain their catch rates by moving to new areas. Thus CPUE stays high while the biomass is decreasing. In PAU 3, both the early and recent CPUE indices have shown a relatively flat trend (the recent CPUE decreased slightly). It is unknown to what extent the CPUE series tracks stock abundance in PAU 3. Information from commercial fishers indicates that the stock is in relatively good shape suggesting that the trend in CPUE series may be credible.

PAUA (PAU 3)

Even if the CPUE indices are credible, they are not very useful in informing estimates of B_0 in this case because they have shown a relatively flat trend. Therefore the catch sampling length frequencies are the most important observations that provide information on the initial size of the stock. The catch sampling coverage in PAU 3 is considered to be reasonably adequate and the CSLF data are likely to have been representative of the stock.

Another source of uncertainty is the catch data. The commercial catch is known with accuracy since 1985, but is probably not well estimated before that. In addition, non-commercial catch estimates are poorly determined. The estimate of illegal catch is uncertain. Anecdotal evidence suggested the recreational catch in PAU 3 is very likely to have increased substantially in recent years and could be much higher than what was assumed in the model. However, the increase in non-commercial catch (if it is true) has not been reflected in the recent CPUE indices, which showed an almost flat trend. One possible reason is that the commercial divers may have fished deeper than recreational fishers, and could be fishing on different sections of the population. If there is substantial bias in estimates of catches, the model could significantly under-estimate the stock depletion level. Therefore better information on the scale and trend in recreational catch needs to be collated for more accurate assessment of the stock status.

Another source of uncertainty is that fishing may cause spatial contraction of populations (Shepherd & Partington 1995), or that some populations become relatively unproductive after initial fishing (Gorfine & Dixon 2000). If this happens, the model will overestimate productivity in the population as a whole. Past recruitments estimated by the model might instead have been the result of serial depletion.

5. STATUS OF THE STOCK

Stock Structure Assumptions

PAU 3 is assumed to be a homogenous stock for purposes of the stock assessment however there is evidence to show this may not be correct (Naylor et al 2006).

• PAU 3 - *Haliotis iris*

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	MCMC 6.1 base case (M estimated, g_1 fixed at 20 mm and g_2 fixed at 6.0 mm)
Reference Points	Target: 40% B_0 (Default as per HSS) Soft Limit: 20% B_0 (Default as per HSS) Hard Limit: 10% B_0 (Default as per HSS) Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	B_{2013} estimated to be 52% B_0 : Very Likely (> 60%) to be at or above the target
Status in relation to Limits	Very Unlikely (< 10%) to be below the soft and hard limits
Status in relation to Overfishing	Overfishing is Very Unlikely (< 10%) to be occurring

Historical Stock Status Trajectory and Current Status

Posterior distributions of spawning stock biomass as a percentage of virgin level from MCMC 6.1 (including projections). The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Trajectory of exploitation rate as a ratio $U/40B_0$ and spawning stock biomass as a ratio of B_0 from the start of assessment period 1965 to 2013 for MCMC 6.1 (base case). The vertical lines at 10%, 20%, 40% B_0 represent the hard limit, the soft limit, and the target respectively. $U/40B_0$ is the exploitation rate at which the spawning stock biomass would stabilise at 40% B_0 over the long term. Each point on trajectory represents the estimated annual stock status: the value on x axis is the mid-season spawning stock biomass (as a ratio of B_0) and the value on the y axis is the corresponding exploitation rate (as a ratio $U/40B_0$) for that year. The Estimates are based on MCMC median and the 2013 90% CI is shown by the cross line.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Spawning stock biomass has shown an overall decreasing trend but this has become much slower in recent years.
Recent Trend in Fishing Intensity or Proxy	The exploitation rate has shown a gradual upward trend since the 2000s and was about 0.16 (0.09–0.14) in 2013.
Other Abundance Indices	Standardised CPUE remained relatively flat until the early 2000s, and has declined only slightly since then.
Trends in Other Relevant Indicators or Variables	Estimated recruitment was relatively low between 1980 and 1990 but since 2002 has been above the long term average.

Projections and Prognosis

Stock Projections or Prognosis	The projected spawning stock abundance will slightly decrease over the next three years but will still be remaining above the target
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Results from all model runs suggest it is very unlikely (< 10%) that current catch or TACC will cause a decline below the limits.
Probability of Current Catch or TACC causing Overfishing to continue or to commence	-

Assessment Methodology and Evaluation		
Assessment Type	Full quantitative stock assessment	
Assessment Method	Length based Bayesian model	
Assessment Dates	Latest: 2014	Next: unknown
Overall assessment quality (rank)	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Catch history - CPUE indices early series - CPUE indices later series - Commercial sampling length frequencies - Tag recapture data (to estimate growth) - Maturity at length data 	<ul style="list-style-type: none"> 1 – High Quality for commercial catch 2 – Medium or Mixed Quality for recreational catch, which is not believed to be fully representative over the history of the fishery 2 – Medium or Mixed Quality: not believed to be proportional to abundance 1 – High Quality 1 – High Quality 2 – Medium or Mixed Quality: not believed to be fully representative of the whole QMA 1 – High Quality
Data not used (rank)	N/A	
Changes to Model Structure and Assumptions	New model	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Very little growth data available and growth is not well known. - CPUE may not be a reliable index of abundance. - The model treats the whole of the assessed area of PAU 3 as if it were a single stock with homogeneous biology, habitat and fishing pressures. - Recreational catch in PAU 3 is very likely to have increased substantially in recent years and could be much higher than what was assumed in the model. 	

Qualifying Comments:

- The lack of comprehensive growth and length frequency data for PAU 3 and the lack of contrast in the CPUE series cause uncertainty in the model outputs.
- The SFWG agreed to adopt model 6.1 as the base case model, but noted that the model underestimates uncertainty in stock biomass and stock status because of uncertainty in growth.

PAUA (PAU 4) – Chatham Islands*(Haliotis iris)*

Pāua

**1. FISHERY SUMMARY**

PAU 4 was introduced into the Quota Management System in 1986–87 with a TACC of 261 t. As a result of appeals to the Quota Appeal Authority, the TACC was increased in 1995–96 to 326 t and has remained unchanged to the current fishing year (Table 1). There is no TAC for this QMA: before the Fisheries Act (1996) a TAC was not required. When changes have been made to a TACC after 1996, stocks have been assigned a TAC.

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 4 since introduction into the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1995	-	-	-	-	261
1995–present	-	-	-	-	326

1.1 Commercial fisheries

The fishing year runs from 1 October through to 30 September. On 1 October 2001 it became mandatory to report catch and effort on PCELRs using fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme (see figure above).

At the beginning of the 2009–10 fishing year, reporting of catch in PAU 4 was changed from reporting in greenweight to reporting in meatweight. The TACC is still set in greenweight but fishers are now required to report greenweight catch that is estimated from the meatweight measured by the licensed fish receiver (LFR). The meatweight to greenweight conversion factor is 2.50 (equivalent to 40% meatweight recovery). The change was made to curb the practice of converting meatweight to landed greenweight after shucking to obtain artificially high recovery rates. It was also made to encourage catch spreading by making it commercially viable for fishers to harvest areas where shells are heavily fouled and meatweight recovery is low. Heavy fouling on shells is a problem that occurs in a number of areas around the Chatham Islands. Landings for PAU 4 are shown in Table 2 and Figure 1.

Table 2: TACC and reported landings (t) of paua in PAU 4 from 1983–84 to the present.

Year	Landings	TACC
1983–84*	409	-
1984–85*	278	-
1985–86*	221	-
1986–87*	267.37	261

* FSU data

Figure 1: Reported commercial catch and TACC for PAU 4 from 1983–84 to the present.

1.2 Recreational fisheries

There are no estimates of recreational catch for PAU 4. The 1996, 1999–2000 and 2000–01 national marine recreational fishing surveys did not include PAU 4.

1.3 Customary fisheries

There are no estimates of customary catch for PAU 4. For the 2004 stock assessment this catch was assumed to be zero. For further information on customary fisheries refer to the introductory PAU Working Group Report.

1.4 Illegal catch

There are no estimates of illegal catch for PAU 4. For the 2004 stock assessment this catch was assumed to be zero. For further information on illegal catch refer to the introductory PAU Working Group Report.

1.5 Other sources of mortality

For further information on other sources of mortality refer to the introductory PAU Working Group Report.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Working Group Report.

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Working Group Report.

4. STOCK ASSESSMENT

4.1 Estimates of fishery parameters and abundance

A standardised CPUE analysis for PAU 4 (Fu 2010) from 1989–90 to 2007–08 was completed in February 2010.

The Shellfish Working Group (SFWG) agreed that, because of extensive misreporting of catch in PAU 4, catch and effort data from the Fisheries Statistical Unit and from the CELR and PCELR forms might be misleading in CPUE analyses and therefore, CPUE cannot be used as an index of abundance in this fishery.

4.2 Stock assessment 2004

The last stock assessment for PAU 4 was completed in 2004 (Breen & Kim 2004). A Bayesian length-based stock assessment model was applied to PAU 4 data to estimate stock status and yield. A reference period from 1991–93 was chosen: this was a period after which exploitation rates increased and then leveled off, and after which biomass declined somewhat and then stabilised. It was not intended as a target. Assessment results suggested that then-current recruited biomass was just above B_{AV} , but with high uncertainty (83% to 125%). and current spawning biomass appeared higher than S_{AV} , (130%), but with cautions related to maturity ogives. Projections suggested that 2007 recruited and spawning biomasses could be above B_{AV} , but this was uncertain.

The SFWG advised that major uncertainties in the assessment required the results to be treated with great caution. The major uncertainties included very sparse research diver survey data, misreported CELR and PCELR data, growth and length frequency data most likely not being representative of the whole population and the assumption that CPUE was an index of abundance.

In February 2010 the SFWG agreed that, because of the lack of adequate data as input into the Bayesian length-based model, a stock assessment for PAU 4 using this model was not appropriate.

4.3 Biomass estimates

There are no current biomass estimates for PAU 4.

4.4 Yield estimates and projections

There are no estimates of PAU 4.

5. STATUS OF THE STOCKS

Stock Structure Assumptions

H. iris individuals collected from the Chatham Islands were found to be genetically distinct from those collected from costal sites around the North and South Islands (Will & Gemmell 2008).

PAU 4 - *Haliotis iris*

Stock Status	
Year of Most Recent Assessment	2004
Assessment Runs Presented	None
Reference Points	Target: 40% B_0 (Default as per HSS) Soft Limit: 20% B_0 (Default as per HSS) Hard Limit: 10% B_0 (Default as per HSS) Overfishing threshold: U40% B_0
Status in relation to Target	Unknown
Status in relation to Limits	Unknown
Status in relation to Overfishing	Unknown
Historical Stock Status Trajectory and Current Status⁸ In 2010 the SFWG rejected CPUE as an index of abundance, therefore the 2004 stock assessment (Breen & Kim 2004) is no longer considered reliable.	

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Unknown
Recent Trend in Fishing Intensity or Proxy	Unknown

PAUA (PAU 5A) – Fiordland

(*Haliotis iris*)
Paua

1. FISHERY SUMMARY

Prior to 1995, PAU 5A was part of the PAU 5 QMA, which was introduced into the QMS in 1986 with a TACC of 445 t. As a result of appeals to the Quota Appeal Authority, the TACC increased to 492 t in the 1991–92 fishing year; PAU 5 was then the largest QMA by number of quota holders and TACC. Concerns about the status of the PAU 5 stock led to a voluntary 10% reduction in the TACC in 1994–95. On 1 October 1995, PAU 5 was divided into three QMAs (PAU 5A, PAU 5B, and PAU 5D; see the figure above) and the TACC was divided equally among them; the PAU 5A quota was set at 148.98 t.

There is no TAC for PAU 5A (Table 1): before the Fisheries Act (1996) a TAC was not required. When changes have been made to a TACC after 1996, stocks have been assigned a TAC. No allowances have been made for customary, recreational or other mortality.

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 5 and PAU 5A since introduction to the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1991*	-	-	-	-	445
1991–1994*	-	-	-	-	492
1994–1995*	-	-	-	-	442.8
1995–present	-	-	-	-	148.98

*PAU 5 TACC figures

1.1 Commercial fisheries

The fishing year runs from 1 October to 30 September.

On 1 October 2001 it became mandatory to report catch and effort on Paua Catch Effort Landing Returns (PCELRs) using fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme (Figure 1).

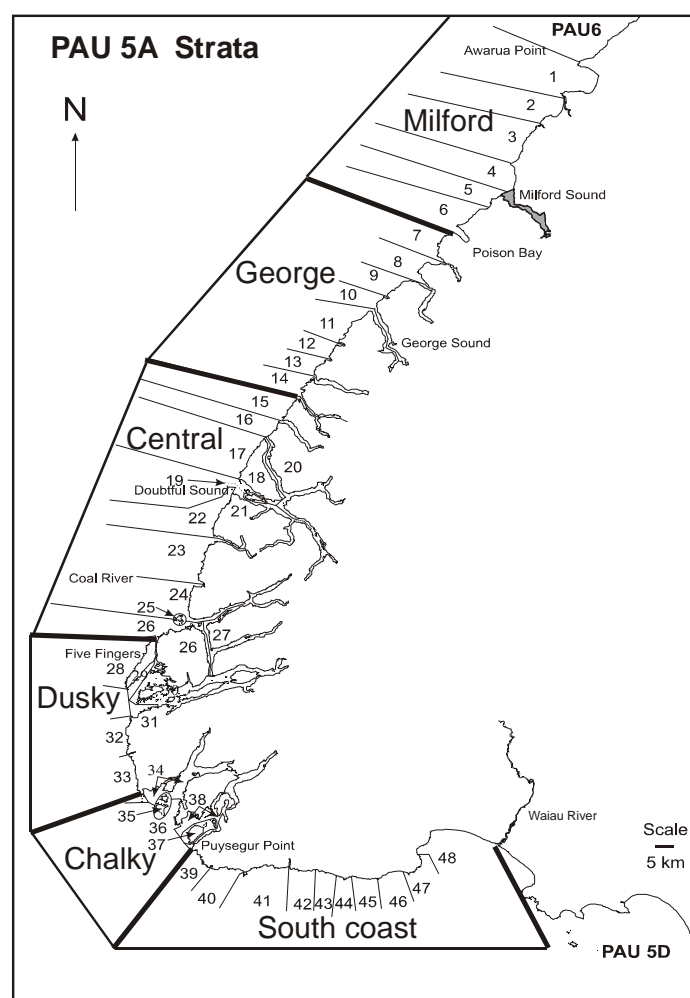

Figure 1: Map of Paua Statistical Areas, and voluntary management strata in PAU 5A.

Landings for PAU 5A are shown in Table 2 and Figure 2. Landings for PAU 5 are reported in the introductory PAU Working Group Report.

Table 2: TACC and reported landings (t) of paua in PAU 5A from 1995–96 to the present from MHR returns.

Year	Landings	TACC
1995–96	139.53	148.98
1996–97	141.91	148.98
1997–98	145.22	148.98
1998–99	147.36	148.98
1999–00	143.91	148.98
2000–01	147.70	148.98
2001–02	148.53	148.98
2002–03	148.76	148.98
2003–04	148.98	148.98
2004–05	148.95	148.98
2005–06	148.92	148.98
2006–07	104.03	148.98
2007–08	105.13	148.98
2008–09	104.82	148.98
2009–10	105.74	148.98
2010–11	104.40	148.98
2011–12	106.23	148.98
2012–13	105.56	148.98
2013–14	102.30	148.98
2014–15	106.95	148.98
2015–16	106.84	148.98
2016–17	106.50	148.98

1.2 Recreational fisheries

The National Panel Survey of Marine Recreational Fishers 2011–12: Harvest Estimates (2014), estimated that about 0.42 t of paua were harvested by recreational fishers in PAU 5A in 2011–12. For the purpose of the 2014 stock assessment, the SFWG agreed to assume that the recreational catch rose linearly from 1 t in 1974 to 5 t in 2006, and remained at 5 t between 2007 and 2013.

Figure 2: Landings and TACC for PAU 5A from 1995–96 to the present. For historical landings in PAU 5 prior to 1995–96, refer to figure 1 and table 1 in the introductory PAU Working Group Report.

1.3 Customary fisheries

Records of customary non-commercial catch taken under the South Island Regulations show that about 100 to 500 paua were collected each year from 2001–02 to 2012–13. For the purpose of the 2014 stock assessment model, the SFWG agreed to assume that customary catch has been constant at 1 t.

1.4 Illegal catch

There are no estimates of illegal catch for PAU 5A. For the purpose of the 2014 stock assessment model, the SFWG agreed to assume that illegal catches have been a constant 5 t.

1.5 Other sources of mortality

For further information on other sources of mortality refer to the introductory PAU Working Group Report.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Working Group Report. Biological parameters derived using data collected from PAU 5A are summarised in Table 3. Size-at-maturity, natural mortality and annual growth increment parameters were estimated within the assessment model.

Table 3: Estimates of biological parameters (*H. iris*). All estimates are external to the model.

Stock area		Estimate	Source
<u>1. Weight = a (length)^b (weight in kg, shell length in mm)</u>			
PAU 5A	a = 2.99E-08	b = 3.303	Schiel & Breen (1991)
<u>2. Size at maturity (shell length)</u>			
PAU 5A	50% mature	93 mm	Samples from Dusky, George, and Milford areas (Fu et al 2010)
	95% mature	109 mm	
<u>3. Estimated annual growth increments (both sexes combined)</u>			Samples from Central, Dusky, George, Chalky and the South Coast (Fu et al 2010)
PAU 5A	At 75 mm	25.2 mm	
	At 120 mm	6.9 mm	

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Working Group Report.

4. STOCK ASSESSMENT

Prior to 2010, stock assessments for PAU 5A had been carried out at the QMA level. In 2010 the Shellfish Working Group decided to split PAU 5A into two subareas (the southern area which included the Chalky and South Coast strata, and the northern area which included the Milford, George, Central, and Dusky strata (Figure 1)) and conduct separate stock assessments in each subarea. The division was based on the availability of data, differences in exploitation history and management initiatives. The 2014 assessment followed the same decision.

4.1 Estimates of fishery parameters and abundance

Parameters estimated in the base case model (for both the southern and northern areas) and their assumed Bayesian priors are summarized in Table 4.

Table 4: A summary of estimated model parameters, lower bound, upper bound, type of prior, (U=uniform; N= normal; LN=lognormal), mean and CV of the prior.

Parameter	Prior	μ	CV	Bounds	
				Lower	Upper
$\ln(R0)$	U	–	–	5	50
M (natural mortality)	LN	0.1	0.35	0.01	0.5
g_{max} (maximum growth increment)	U	–	–	1	50
$g_{50\%}$ (length at which the annual increment is half the maximum)	U	–	–	1	150
$g_{50-95\%}$ (difference in length at 50% and 95% of the maximum increment)	U	–	–	0.01	150
ϕ (CV of mean growth)	U	–	–	0.001	1
$\ln(q^I)$ (catchability coefficient of CPUE)	U	–	–	-30	0
$\ln(q^J)$ (catchability coefficient of PCPUE)	U	–	–	-30	0
L_{50} (Length at 50% maturity)	U	–	–	70	145
L_{95-50} (Length between 50% and 95% maturity)	U	–	–	1	50
D_{50} (Length at 50% selectivity for the commercial catch)	U	–	–	70	145
D_{95-50} (Length between 50% and 95% selectivity for the commercial catch)	U	–	–	0.01	50
D_s (change in commercial diver selectivity for one unit change of MHS)	U	–	–	0.01	50

For both assessments, the following observational data were included:

1. Standardised CPUE series covering 1990–2001 based on CELR data.
2. Standardised CPUE series covering 2002–2014 based on PCELR data.
3. Commercial catch sampling length frequency series for 1992–1994, 1998, 2001–2014
4. Tag-recapture length increment data (all areas combined).
4. Maturity at length data (all areas combined)

4.1.1 Relative abundance estimates from standardised CPUE analyses

The 2014 stock assessment used two sets of standardised CPUE indices: one based on CELR data covering 1990–2001, and another based on PCELR data covering 2002–2014. For both series, standardised CPUE analyses were carried out using Generalised Linear Models (GLMs). A stepwise procedure was used to select predictor variables, with variables entering the model in the order that gave the maximum decrease in the residual deviance. Predictor variables were accepted in the model only if they explained at least 1% of the deviance.

For both the CELR and PCELR data, the Fisher Identification Number (FIN) was used in the standardisations instead of vessel identification. This process was followed because the FIN is associated with a permit holder who may employ a suite of grouped vessels, which implies that there could be linkage in the catch rates among vessels operated under a single FIN.

For the CELR data there is ambiguity in what is recorded for estimated daily fishing duration. On many CELR forms it is unclear if the hours of diving recorded is the total time each individual diver spent harvesting, or the total time spent harvesting by all divers. Because of this daily fishing duration has not been used in past standardisations as a measure of effort, instead the number of divers has been used. However, there is evidence that the fishing duration for a diver changes over time, and because of this a new data set was generated for which the recorded fishing duration was less ambiguous. This was done by combining a subset of the data for which the recorded daily duration was predominantly total hours of diving *for all* divers, with the rest of the data in which the daily fishing duration was incorrectly recorded as hours *per diver* (and scaling the hours recorded by the number of divers to get the correct daily fishing duration *for all* divers). The criteria used to subset the data were: (i) just one diver or (ii) fishing duration ≥ 8 hours and number of divers ≥ 2 . The new combined data set was used for the CELR standardisation using estimated daily catch, and effort as either number of divers or estimated fishing duration (both were offered to the standardisation model).

For the PCELR data the unit of catch was diver catch, with effort as diver duration.

FIN codes were used to select a core group of fishers from the CELR data, with the requirement to qualify for the core fisher group that there be a minimum of 5 records per year for a minimum of 2 years (northern area), or a minimum of 5 records per year for a minimum of three years (southern area). In both cases 80% of the catch was retained over 1990–2001. For the PCELR data the FIN was also used to select a core group of fishers, with the requirement that there be a minimum of 10 records per year for a minimum of 6 years (northern area), or a minimum of 10 records per year for a minimum of 4 years (southern area). This retained 83% (northern area) or 85% (southern area) of the catch over 2002–2014.

For the CELR data, year was forced into the model and other predictor variables offered to the model were FIN, statistical area month, fishing duration (as a cubic polynomial), number of divers, and a month:area interaction. For the PCELR data fishing year was forced into the model and variables offered to the model were month, diver key, FIN statistical area, diver duration (third degree polynomial), and diving conditions.

The northern area standardised CPUE shows fluctuation with no real trend from 1990 to 2001, and is flat from 2002 to 2014 (Figure 3-top). The southern area standardised CPUE shows a decline from 1990 to 2008, then an increase from 2009 to 2014 (Figure 3-bottom).

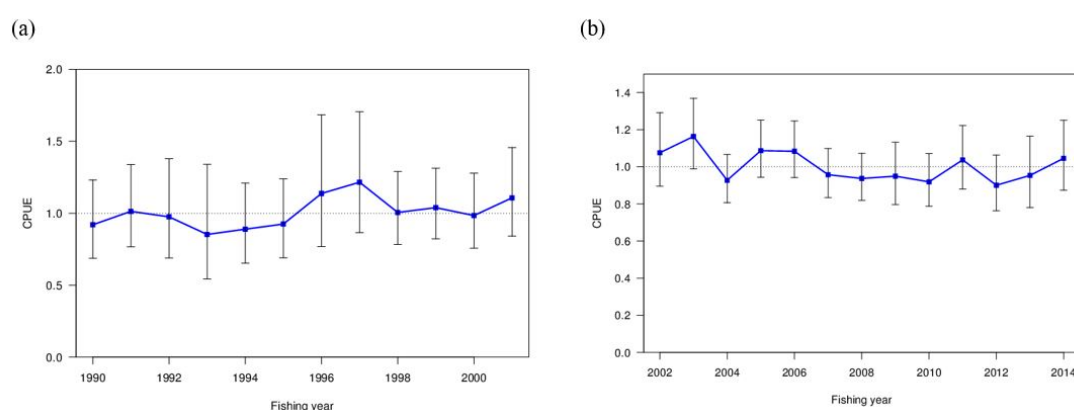

Figure 3: Standardised CPUE indices for the northern area of PAU 5A based on the CELR 1990–2001 (a) and PCELR 2002–2014 (b) and for the southern area based on CELR 1990–2001 (c) and PCELR 2002–2014 (d).

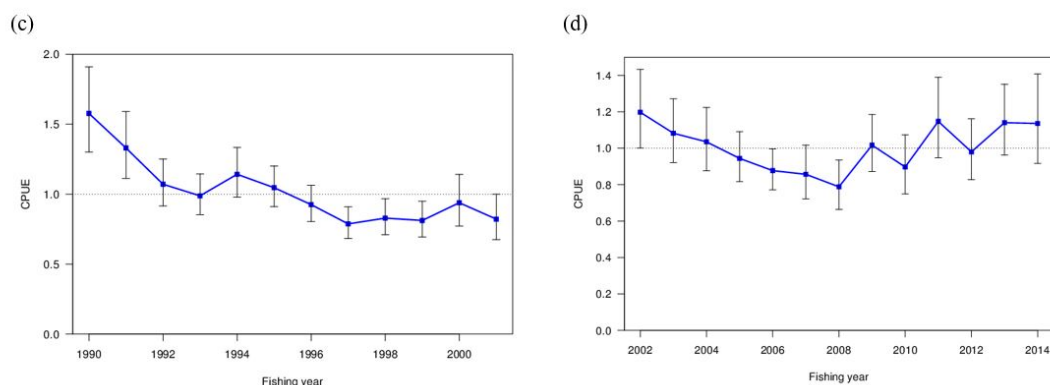

Figure 3 [Continued]: Standardised CPUE indices for the northern area of PAU 5A based on the CELR 1990–2001 (a) and PCELR 2002–2014 (b) and for the southern area based on CELR 1990–2001 (c) and PCELR 2002–2014 (d).

4.1.2 Relative abundance estimates from research diver surveys

The abundance of paua in PAU 5A was also estimated from research diver surveys in 1996, 2002, 2003, 2006, and 2008–2010. Not every stratum was surveyed in each year, and before 2005–06 surveys were conducted only in the area from Dusky South. These data were not included in the assessment because there is concern that the data are not a reliable index of abundance

Concerns about the reliability of this data as an estimate of relative abundance instigated several reviews in 2009 (Cordue 2009) and 2010 (Haist 2010). The reviews assessed i) the reliability of the research diver survey index as a proxy for abundance and ii) whether the Research Diver Survey Index (RDSI), when used in the paua stock assessment models, results in model outputs that do not adequately reflect the status of the stocks. Both reviews suggest that outputs from paua stock assessments using the RDSI should be treated with caution. For a summary of the conclusions from the reviews refer to the introductory PAU Working Group Report.

4.2 Stock assessment methods

The 2014 assessment for the southern and northern areas of PAU 5A (Fu 2015a, b) incorporated revision of the length-based model used in 2010 for PAU 5A (Fu & McKenzie 2010a, 2010b) and used in revised form for subsequent assessment in PAU 5D (Fu 2013) and PAU 5B (Fu 2014). For more information on the model structure and the data used refer to Fu et al (2015) and Fu (2015a, b).

The model structure assumed a single-sex population residing in a single homogeneous area, with length classes from 70 mm to 170 mm in groups of 2 mm. Growth is length-based, without reference to age, mediated through a growth transition matrix that describes the probability of each length class to change at each time step. Paua entered the partition following recruitment and were removed by natural mortality and fishing mortality.

The model simulates the population from 1965 to 2014. Catches were available for 1974–2014 although catches before 1995 must be estimated from the combined PAU 5 catch, and were assumed to increase linearly between 1965 and 1973 from 0 to the 1974 catch level. Catches included commercial, recreational, customary, and illegal catch, and all catches occurred within the same time step. It was assumed that 80% of the non-commercial catch was taken from the southern area of PAU 5A, with the remainder being taken from the northern area

Recruitment was assumed to take place at the beginning of the annual cycle, and length at recruitment was defined by a uniform distribution with a range between 70 and 80 mm. No explicit stock-recruitment relationship was modelled in previous assessments; however, the

Shellfish Working Group agreed to use a Beverton-Holt stock-recruitment relationship with steepness (h) of 0.75 for this assessment.

Maturity is not required in the population partition but is necessary for estimating spawning biomass. The model estimated proportions mature from length-at-maturity data. Growth and natural mortalities were also estimated within the model. The model estimated the commercial fishing selectivity, assumed to follow a logistic curve and to reach an asymptote. The increase in Minimum Harvest Size since 2006 was modelled as an annual shift in fishing selectivity, which is equal to an annualised unit increase (estimated within the model), multiplied by the number of units associated with each year.

The assessment was conducted in several steps. First, the model was fitted to the data with parameters estimated at the mode of their joint posterior distribution (MPD). The fit obtained is the mode of the joint posterior distribution of parameters (MPD). Next, from the resulting fit, Markov chain-Monte Carlo (MCMC) simulations were made to obtain a large set of samples from the joint posterior distribution. From this set of samples, forward projections were made to obtain a set of agreed indicators. Sensitivity trials were explored by comparing MPD fits made with alternative model assumptions.

For the Southern area the commercial catch history estimates were made under assumptions about the split of the catch between sub-stocks of PAU 5, and between subareas within PAU 5A. The base case model run assumed that 40% of the catch in Statistical Area 030 was taken from PAU 5A between 1985 and 1996. Estimates made under alternative assumptions (a lower bound of 18% and an upper bound of 61%) were used in sensitivity trials. The maturity and growth data included in the model were based on samples collected throughout PAU 5A, and the abundance and length frequency data were from Chalky and South Coast. Catch samples before 2002 (1992–1994, 1998, and 2001) were excluded from the base case, because the sample size is low and sampling coverage is dubious. The base case also used the methods recommended by Francis (2011) to determine the weight of the proportion-at-length and abundance data, and used the inverse-logistic growth model. The RDSI and RDLF were excluded from the base case, and the CPUE shape parameter was fixed at 1 assuming a linear relationship between CPUE and abundance. Recruitment deviations were estimated for 1986–2010.

For the Northern area the commercial catch history estimates between 1984 and 2010 were based on reported catch from Statistical Area 031 and 032, and estimates before 1984 were made using assumptions about the split of the catch between subareas within PAU 5A. The split proportions were inferred from the total estimated catch between 1984 and 1995 from Statistical Areas 030, 031, and 032, assuming that 18% (upper bound), 40% (base case), or 61% (lower bound) of the annual catch in 030 was taken from PAU 5A. The catch vector estimated under the base case assumption was used in the base case model. The maturity and growth data included in the model were based on samples collected throughout PAU 5A, and the abundance and length frequency data were from Milford, George, Central, and Dusky. Catch samples collected before 2002 (1992, 1993, 1998, 2000, and 2001) were excluded from the base case. The base case also used the methods recommended by Francis (2011) to determine the weight of the proportion-at-length and abundance data, and used the inverse-logistic growth model. The RDSI and RDLF were excluded from the base case and the CPUE shape parameter was fixed at 1. Recruitment deviations were estimated for 1986–2010.

The following sensitivity analyses were conducted for both the Southern and Northern areas. Run 1.6 used the SDNRs-based method to determine the weights of the proportion-at-length and abundance data; Run 1.7 included all the commercial length frequencies; Run 2.0 included the RDSI and RDLF data. For the Southern area, two additional sensitivity runs were conducted: Run 1.8 used commercial catch history that was estimated under “assumption 1” (between 1984 and 1996, 18% of the catch in Statistical Area 030 was taken from PAU 5A);

Run 1.9 used commercial catch history estimated under “assumption 3” (between 1984 and 1996, 61% of the catch in Statistical Area 030 was taken from PAU 5A); For both assessments, The MCMC runs were carried out on models 1.5 (base case), 1.6, and 1.7.

The assessment calculates the following quantities from their posterior distributions: the equilibrium spawning stock biomass assuming that recruitment is equal to the average recruitment from the period for which recruitment deviation were estimated (B_0), the mid-season spawning and recruited biomass for 2014 (B_{2014} and B_{2014}^r) and for the projection period (B_{proj} and B_{proj}^r). This assessment also reports the following fishery indicators:

$B\% B_0$	Current or projected spawning biomass as a percentage of B_0
$B\% B_{msy}$	Current or projected spawning biomass as a percentage of B_{msy}
$\Pr(B_{proj} > B_{msy})$	Probability that projected spawning biomass is greater than B_{msy}
$\Pr(B_{proj} > B_{2014})$	Probability that projected spawning biomass is greater than $B_{current}$
$B\% B_0^r$	Current or projected recruited biomass as a percentage of B_0^r
$B\% B_{msy}^r$	Current or projected recruited biomass as a percentage of B_{msy}^r
$U_{Current}$	Current Exploitation
$U_{40\% B_0}$	Exploitation that will achieve 40% B_0
MSY	Maximum Sustainable Yield
$\Pr(B_{proj} > B_{msy}^r)$	Probability that projected recruit-sized biomass is greater than B_{msy}^r
$\Pr(B_{proj} > B_{2012}^r)$	Probability that projected recruit-sized biomass is greater than B_{2012}^r
$\Pr(B_{proj} > 40\% B_0)$	Probability that projected spawning biomass is greater than 40% B_0
$\Pr(B_{proj} < 20\% B_0)$	Probability that projected spawning biomass is less than 20% B_0
$\Pr(B_{proj} < 10\% B_0)$	Probability that projected spawning biomass is less than 10% B_0
$\Pr(U_{proj} > U_{40\% B_0})$	Probability that projected exploitation rate is greater than $U_{40\% B_0}$

4.2.1 Stock assessment results

Southern Area

The base case fitted the two CPUE indices and the CSLF well, but the model predicted a broader distribution than the observed LF for a number of years. The use of the inverse-logistic growth model produced an adequate fit to the tag-recapture data. The estimates of recruitment deviations showed a period of relatively high recruitment in the mid-1990s and also in the 2000s. Estimated exploitation rates have declined since 2002, but have increased slightly over the last few years

The summary of indicators from the base case is shown in Table 5. The median of the posterior of B_0 was estimated to be 1 381 t. The posterior trajectory of spawning stock biomass is shown in Figure 4. Current estimates from the base case suggested that the spawning stock population in 2014 ($B_{current}$) was 41% (33–50%) B_0 , and recruit-sized stock abundance ($B_{current}^r$) was 32% (24–41%) of the initial state (B_0^r).

When the CSLF data were up-weighted (MCMC 1.6), $B_{current}$ was estimated to be 35% (30–41%) of B_0 . This model fitted less adequately to the tag-recapture data, with some negative bias for the larger size classes. Model results from the MCMC 1.7 were very similar to the base case and $B_{current}$ was estimated to be 42% (33–52%) B_0 .

The assessment results were sensitive to the alternative catch history estimates. MPD estimates of $B_{current}$ were 34% and 46% B_0 when the upper and lower bound catch estimates were assumed, respectively.

Table 5: Summaries of the marginal posterior distributions of indicators for the base case of the southern area assessment. Columns show the 5th and 95th quantiles, median, minimum and maximum of each distribution. Biomass is in tonnes.

	Min	5%	Median	95%	Max

Figure 4: Posterior distributions of spawning stock biomass (including projection) as a percentage of B_0 for the southern area assessment base case model. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Northern area

The base case fitted the two CPUE indices well, but predicted more large paua in the length distributions than the observed LF for a number of years. The estimates of recruitment deviations showed a period of relatively high recruitment in the early 1990s and the early 2000s, but in most years, the recruitment was close to the long-term average. Estimated exploitation rates have declined since 2005.

The summaries of indicators from the base case for the northern area assessment are shown in Table 6. The median of the posterior of B_0 was estimated to be 1 239 t. The posterior trajectory of spawning stock biomass is shown in Figure 5. Current estimates from the base case suggest that the spawning stock population in 2014 (B_{current}) was 47% (40–54%) B_0 , and recruit-sized stock abundance (B^r_{current}) was 37% (31–45%) of the initial state (B^r_0).

When the CSLF data were up-weighted (MCMC 1.6), B_{current} was estimated to be 39% (34–45%) B_0 . Model results from MCMC 1.7 were very similar to the base case, and B_{current} was estimated to be 47% (39–55%) B_0 .

Table 6: Summaries of the marginal posterior distributions of indicators for the base case of the northern area assessment. Columns show the 5th and 95th quantiles, median, minimum and maximum of each distribution. Biomass is in tonnes.

	Min	5%	Median	95%	Max

The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

4.3 Yield estimates and projections

Southern Area

Assuming that the future catch remains at its current level, projections suggested that the spawning stock abundance will increase to 48% (0.38–0.61) over the next three years, and the probability of the spawning biomass being above the target (40%) will increase from 55% in 2014 to 67% in 2017 (Table 7). Assuming a 10% increase in the catch, the biomass will only increase slightly over the next three years; assuming a 20% increase in catch; the projected biomass will remain relatively stable.

Table 7: Summary of key indicators from the projection for the base case (1.5) MCMC of the southern area assessment with future commercial catch assumed to be the same the current catch: projected biomass as a percentage of the virgin and current stock status, for spawning stock and recruit-sized biomass.

	2014	2015	2016	2017
$B_{proj} \% B_0$	0.41 (0.32–0.53)	0.41 (0.32–0.54)	0.42 (0.32–0.55)	0.43 (0.32–0.56)
$B_{proj} \% B_{msy}$	1.51 (1.17–1.95)	1.53 (1.18–1.98)	1.56 (1.19–2.03)	1.58 (1.19–2.07)
$\Pr(> B_{msy})$	1.00	1.00	1.00	1.00
$\Pr(> B_{current})$	0.00	0.84	0.81	0.81
$\Pr(> 40\% B_0)$	0.55	0.60	0.64	0.67
$\Pr(< 20\% B_0)$	0.00	0.00	0.00	0.00
$\Pr(< 10\% B_0)$	0.00	0.00	0.00	0.00
$\% B_0^r$	0.32(0.23–0.43)	0.32 (0.23–0.44)	0.33 (0.24–0.44)	0.33 (0.24–0.45)
$\% B_{msy}^r$	1.83 (1.27–2.70)	1.86 (1.27–2.77)	1.89 (1.28–2.82)	1.92 (1.30–2.85)
$\Pr(> B_{msy}^r)$	1.00	1.00	1.00	1.00
$\Pr(> B_{current}^r)$	0.00	0.72	0.80	0.90
$\Pr(U_{proj} > U_{40\% B_0})$	0.14	0.08	0.04	0.02

Northern area

Assuming that the future catch remains at current level the projection suggested that the spawning stock abundance will remain relatively stable over the next three years, and the projected biomass in 2017 was 47% B_0 (Table 8). The probability of the spawning biomass in 2017 being above the target (40% B_0) was greater than 90%, and the stock status is very unlikely to be below the soft (20% B_0) or hard limit (10% B_0) in the short term. Assuming a 10% increase in the annual catch, the projected biomass will decrease slightly over the next three years, and the projected biomass in 2017 was 46% B_0 . Assuming a 20% increase in annual catch, the projected biomass decreased to 44% in 2017.

Table 8: Summary of key indicators from the projection for the base case (1.5) MCMC of the northern area assessment with future commercial catch assumed to be the same the current catch: projected biomass as a percentage of the virgin and current stock status, for spawning stock and recruit-sized biomass.

	2014	2015	2016	2017
$B_{proj} \% B_0$	0.47 (0.39–0.56)	0.47 (0.39–0.56)	0.47 (0.39–0.56)	0.47 (0.38–0.57)
$B_{proj} \% B_{msy}$	1.74 (1.46–2.08)	1.74 (1.45–2.08)	1.74 (1.44–2.10)	1.75 (1.41–2.13)
$\Pr(> B_{msy})$	1.00	1.00	1.00	1.00
$\Pr(> B_{current})$	0.00	0.48	0.47	0.50
$\Pr(> 40\% B_0)$	0.95	0.95	0.94	0.92

$\Pr(< 10\% B_0)$	0.00	0.00	0.00	0.00
$\% B_0^r$	0.37 (0.30–0.47)	0.32 (0.25–0.41)	0.32 (0.25–0.41)	0.32 (0.24–0.41)
$\% B_{msy}^r$	2.42 (1.81–3.36)	2.10 (1.54–2.93)	2.10 (1.51–2.95)	2.09 (1.50–2.96)
$\Pr(> B_{msy}^r)$	1.00	1.00	1.00	1.00
$\Pr(> B_{current}^r)$	0.00	0.00	0.00	0.00
$\Pr(U_{proj} > U_{40\% B_0})$	0.07	0.08	0.09	0.09

4.5 Other factors

A number of factors affected the overall validity of the assessment.

There were uncertainties in the estimated catch history for PAU 5A and its subareas before 1995. The results from the southern area assessment suggested that estimates of stock status are sensitive to the range of assumptions made for the estimated catch history. Between the lower-bound and upper-bound catch estimates, model estimates of current spawning stock status ranged from 34 to 46% B_0 . For the northern area of PAU 5A, the commercial catch history is well determined back to 1984, although uncertainty exists for the pre-1984 catch, which is expected to have minor effects on the overall assessment. There is little information on the historical catches in Fiordland, but anecdotal evidence suggested that the catch between 1981 and 1984 was about 60–70 t annually (Storm Stanley pers. comm.). The lower and upper-bound catch estimates used in the assessment may have encompassed many of the uncertainties in the historical catches. In addition, non-commercial catch estimates are also very uncertain, and large differences may exist between the catches assumed and the catch actually taken. In both assessments, the modelled area is treated as if it were a single stock with homogeneous biology, habitat and fishing pressure.

It is assumed that:

- recruitment affects the modelled area in the same way;
- natural mortality does not vary by length or year in the modelled area;
- growth has the same mean and variance in the modelled area, although in reality growth may be stunted in some areas and fast in others.

The models showed some conflicts between length frequencies and CPUE. The early CPUE for the southern area showed a declining trend, indicating that large fish were probably being removed from the stock, which would most likely have resulted in a decline of mean length in the commercial catch over time. But this is not consistent with trend in the observed length distributions. A plausible explanation for this contradiction is that the commercial catch samples in the early years were unrepresentative of the fishery.

Variation in growth is addressed to some extent by having a stochastic growth transition matrix based on increments observed in several different sites. Similarly, the length frequency data are integrated across samples from many places. An open question is whether a model fitted to data aggregated from a large area, within which smaller populations respond differently to fishing, results in credible estimates of the response of the aggregated sub-populations.

This effect is likely to make model results optimistic. For instance, if some local stocks are fished very hard and others are not fished, recruitment failure can result due to the depletion of spawners, because spawners must breed close to each other, and because the dispersal of larvae may be limited. Recruitment failure is a common observation in abalone fisheries internationally. Local processes may decrease recruitment, an effect that cannot be accounted for in the current model.

A significant source of uncertainty is that fishing may cause spatial contraction of populations or that some populations become relatively unproductive after initial fishing due, for example, to reductions in density that may impede successful spawning. If this happens, the model will overestimate productivity in the population as a whole. Historical catches may have been interpreted in the model as good recruitments, whereas they may actually have been the result of serial depletion.

5. STATUS OF THE STOCKS

Stock Structure Assumptions

A genetic discontinuity between North Island and South Island paua populations was found approximately around the area of Cook Strait (Will & Gemmell 2008).

• PAU 5A - *Haliotis iris*

Stock Status	
Year of Most Recent Assessment	2014
Assessment Runs Presented	Southern Area: base case model (run 1.5) Northern Area: base case model (run 1.5)
Reference Points	Target: 40% B_0 (Default as per HSS) Soft Limit: 20% B_0 (Default as per HSS) Hard Limit: 10% B_0 (Default as per HSS) Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	Southern Area: B_{2014} was estimated at 41% (32–53%) B_0 Northern Area: B_{2014} was estimated at 47% (39–56%) B_0

Status in relation to Limits	Southern Area: B_{2014} is Very Unlikely ($< 10\%$) to be below the soft and hard limits. Northern Area: B_{2014} is Very Unlikely ($< 10\%$) to be below the soft limit and hard limits.
Status in relation to Overfishing	Southern Area: The fishing intensity in 2014 was Unlikely ($< 40\%$) to be above the overfishing threshold Northern Area: The fishing intensity in 2014 was Very Unlikely ($< 10\%$) to be above the overfishing threshold

Historical Stock Status Trajectory and Current Status

Posterior distributions from the base case model of spawning stock biomass (including projection) as a percentage of B_0 for the southern area assessment. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution. The boxes to the right of the dashed line indicate the projected spawning biomass to 2017 for each model assuming current catch level.

Trajectory of exploitation rate as a ratio of $U_{40\%B_0}$ and spawning stock biomass as a ratio of B_0 from the start of assessment period 1965 to 2014 for the southern area base case model. The vertical lines at 10%, 20%, and 40% B_0 represent the hard limit, the soft limit, and the target respectively. $U_{40\%B_0}$ is the exploitation rate at which the spawning stock biomass would stabilise at 40% B_0 over the long term. Each point on the trajectory represents the estimated annual stock status: the value on the x axis is the mid-season spawning stock biomass (as a ratio of B_0) and the value on the y axis is the corresponding exploitation rate (as a ratio $U_{40\%B_0}$) for that year. The estimates are based on MCMC medians and the 2014 90% CI is shown by the cross line.

Posterior distributions from the base case model of spawning stock biomass (including projection) as a percentage of B_0 for the northern area assessment. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution. The boxes to the right of the dashed line indicate the projected spawning biomass to 2017 for each model assuming current catch level.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy

Southern Area: Spawning stock biomass has declined from the early years of the fishery up to 2007. Since 2007 biomass has been increasing.

Northern Area: Spawning stock biomass has declined from the early years of the fishery up to 2007. Since 2007 the biomass has increased slightly.

Recent Trend in Fishing Intensity or Proxy	Southern Area: Exploitation rates have an overall declining trend since early 2000s, but have increased slightly over the last four years. Northern Area: Exploitation rates have declined since the mid-2000s.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis		
Stock Projections or Prognosis	Southern Area: At current levels of catch spawning stock biomass is projected to increase to 43% (32–56%) B_0 by 2017. If shelving is reduced by 20% spawning stock biomass is projected to remain stable at 41% (32–52%) of B_0 for the next 3 years. Northern Area: At current levels of catch spawning stock biomass is projected to remain unchanged at 47% (39–56%) B_0 for the next 3 years. If shelving is reduced by 10% spawning stock biomass is projected to decline to 46% (37–56%) B_0 . If shelving is reduced by 20% spawning stock biomass is projected to decline to 44% (35–55%) B_0 .	
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Southern Area: Soft Limit: Very Unlikely (< 10%) Hard Limit: Very Unlikely (< 10%) Northern Area current catch: Soft Limit: Very Unlikely (< 10%) Hard Limit: Very Unlikely (< 10%)	
Probability of Current Catch or TACC causing Overfishing to continue or to commence	Southern Area: Unlikely (< 40%) at current catch levels Unlikely (< 40%) if shelving reduced by 10% About as Likely as Not (40–60%) if shelving reduced by 20% Northern Area: Very Unlikely (< 10%) at current catch levels Unlikely (< 40%) if shelving reduced by 10% About as Likely as Not (40–60%) if shelving reduced by 20%	
Assessment Methodology and Evaluation		
Assessment Type	Level 1 - Full Quantitative Stock Assessment	
Assessment Method	Length-based Bayesian model	
Assessment Dates	Latest assessment: 2014	Next assessment: 2019
Overall assessment quality rank	1 – High Quality	
Main data inputs (rank)	- Catch history - CPUE indices early series - CPUE indices later series - Commercial sampling	1 – High Quality for commercial catch 2 – Mixed or Medium Quality for customary catch 1. No data for recreational or illegal catch 2 – Medium or Mixed Quality: not believed to be fully representative of the entire QMA 1 – High Quality 2 – Medium or Mixed Quality: not believed to be fully representative of the entire OMA

	length frequencies - Tag recapture data (for growth estimation) - Maturity at length data	1 – High Quality 1 – High Quality
Data not used (rank)	- Research Dive Survey Indices - Research Dive Length Frequencies	3 – Low Quality: not believed to index the stock 3 – Low Quality: not believed to be representative of the entire QMA
Changes to Model Structure and Assumptions	-	
Major sources of Uncertainty	- <i>M</i> may not be estimated accurately. There is information in the data that has informed the estimation of <i>M</i> and the prior has also strongly influenced the estimate. - CPUE may not be a reliable index of abundance. - Any effect of voluntary increases in MHS may not have been adequately captured by the model, which could therefore be underestimating the spawning biomass in recent years.

Paua

1. FISHERY SUMMARY

Before 1995, PAU 5B was part of the PAU 5 QMA, which was introduced into the QMS in 1986 with a TACC of 445 t. As a result of appeals to the Quota Appeal Authority, the TACC increased to 492 t in the 1991–92 fishing year; PAU 5 was then the largest paua QMA by number of quota holders and TACC. Concerns about the status of the PAU 5 stock led to a voluntary 10% reduction in the TACC in 1994–95. On 1 October 1995, PAU 5 was divided into three QMAs (PAU 5A, PAU 5B, and PAU 5D; see the figure above) and the TACC was divided equally among them; the PAU 5B TACC was set at 148.98 t.

On 1 October 1999 a TAC of 155.98 t was set for PAU 5B, comprising a TACC of 143.98 t (a 5 t reduction) and customary and recreational allowances of 6 t each. The TAC and TACC have been reduced twice since then and the current TAC is 105 t with a TACC of 90 t, customary and recreational allowances at 6 t each and an allowance of 3 t for other mortality (Table 1).

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 5 and PAU 5B since introduction into the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1991*	-	-	-	-	445
1991–1994*	-	-	-	-	492
1994–1995*	-	-	-	-	442.8
1995–1999	-	-	-	-	148.98
1999–2000	155.9	6	6	-	143.98
2000–2002	124.87	6	6	-	112.187
2002–present	105	6	6	3	90

*PAU 5 TACC figures

1.1 Commercial fishery

The fishing year runs from 1 October to 30 September.

Concerns about the status of the stock led to the commercial fishers agreeing to voluntarily reduce their Annual Catch Entitlement (ACE) by 25 t for the 1999/00 fishing year. This shelving continued for the 2000/01 and 2001/02 fishing years at a level of 22 t but was discontinued at the beginning of the 2002/03 fishing year (Table 2).

PAUA (PAU 5B)

On 1 October 2001 it became mandatory to report catch and effort on Paua Catch Effort Landing Returns (PCELRs) using fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme (Figure 1).

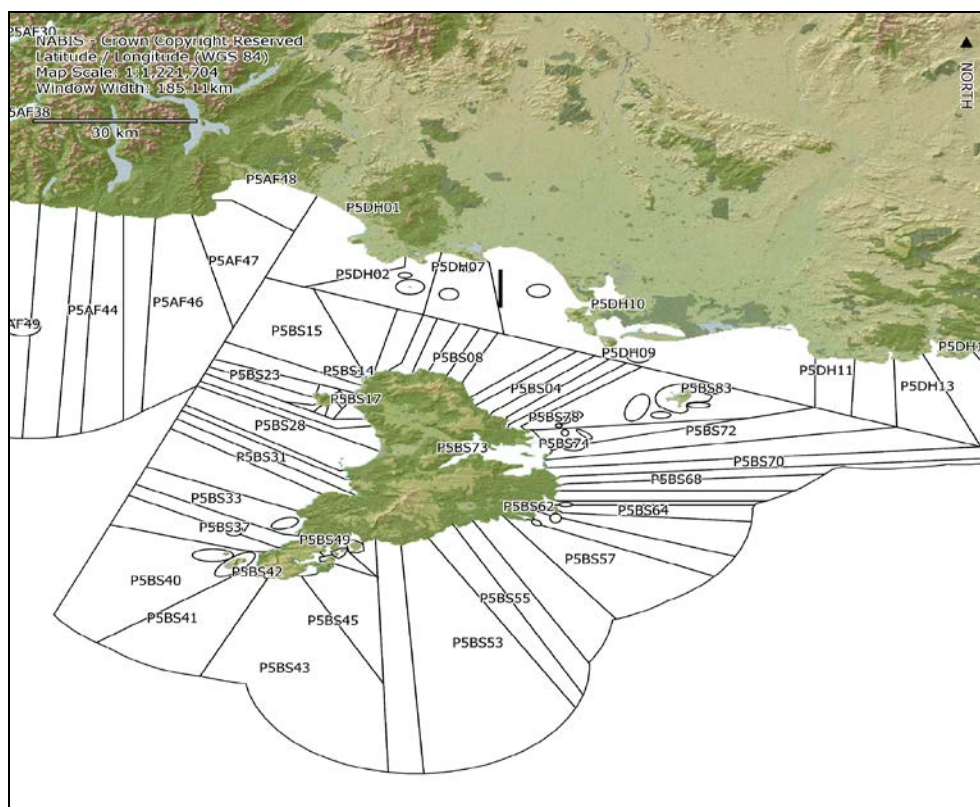

Figure 1: Map of fine scale statistical reporting areas for PAU 5B.

Landings for PAU 5B are shown in Table 2 and Figure 2. Landings for PAU 5 are reported in the introductory PAU Working Group Report.

Table 2: TACC and reported commercial landings (t) of paua in PAU 5B, 1995–96 to present, from QMR and MHR returns.

Year	Landings	TACC
1995–96	144.66	148.98
1996–97	142.36	148.98
1997–98	145.34	148.98
1998–99	148.55	148.98
1999–00	118.07	143.98
2000–01	89.92	112.19
2001–02	89.96	112.19
2002–03	89.86	90.00
2003–04	90.00	90.00
2004–05	89.97	90.00
2005–06	90.47	90.00
2006–07	89.16	90.00
2007–08	90.21	90.00
2008–09	90.00	90.00
2009–10	90.23	90.00
2010–11	89.67	90.00
2011–12	89.59	90.00
2012–13	90.58	90.00
2013–14	88.84	90.00
2014–15	89.45	90.00
2015–16	88.39	90.00
2016–17	92.99	90.00

Figure 2: Reported commercial landings and TACC for PAU 5B from 1995–96 to present. For reported commercial landings in PAU 5 before 1995–96 refer to figure 1 and table 1 in the introductory PAU Plenary Report.

1.2 Recreational fisheries

The ‘National Panel Survey of Marine Recreational Fishers 2011–12: Harvest Estimates’ estimated that the recreational harvest for PAU 5B was 0.82 t with a CV of 50%. For the 2017 assessment model, the SFWG agreed to assume that the recreational catch rose linearly from 1 t in 1974 to 5 t in 2006, and remained at 5 t between 2007 and 2017. For further information on recreational fisheries refer to the introductory PAU Plenary Report.

1.3 Customary fisheries

For the 2017 assessment model the SFWG agreed to assume that customary catch was equal to 1 t from 1974–2017. For further information on customary fisheries refer to the introductory PAU Plenary Report.

1.4 Illegal catch

Illegal catch was estimated by the Ministry of Fisheries to be 15 t, but “Compliance express extreme reservations about the accuracy of this figure.” For the 2017 assessment model, the SFWG agreed to assume that illegal catch was zero before 1986, then rose linearly from 1 t in 1986 to 5 t in 2006, and remained constant at 5 t between 2007 and 2017. For further information on illegal catch refer to the introductory PAU Plenary Report.

1.5 Other sources of mortality

For further information on other sources of mortality refer to the introductory PAU Plenary Report.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Plenary Report. A summary of biological parameters used in the PAU 5B assessment is presented in Table 3.

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Plenary Report.

Table 3: Estimates of biological parameters (*H. iris*).

	Estimate	Source	
<u>1. Natural mortality (<i>M</i>)</u>	0.10 (CV 0.10)	Assumed prior probability distribution	
<u>2. Weight = a(length)^b (Weight in g, length in mm shell length).</u>			
	All		
	a	b	
	2.99 x 10 ⁻⁵	3.303	Schiel & Breen (1991)
<u>3. Size at maturity (shell length)</u>			
	50% maturity at 91 mm		Naylor (NIWA unpub. data)
	95% maturity at 133 mm		Naylor (NIWA unpub. data)
<u>4. Growth parameters (both sexes combined)</u>			
	Growth at 75 mm	Growth at 120 mm	Median (5–95% range) of posterior distributions estimated by the assessment model
	26.1 mm (24.8 to 27.2)	6.9 mm (6.5–7.3)	

4. STOCK ASSESSMENT

The stock assessment was done with a length-based Bayesian estimation model, with parameter point estimates based on the mode of the joint posterior distribution and uncertainty estimated from marginal posterior distributions generated from Markov chain-Monte Carlo simulations. The most recent stock assessment was conducted in 2017 for the fishing year ended 30 September 2017. A base case model (0.1) was chosen from the assessment. The SFWG also suggested several sensitivity runs; model 0.4 which assumed an alternate catch history and model 0.6 where a time varying catchability was estimated.

4.1 Estimates of fishery parameters and abundance

Parameters estimated in the assessment model and their Bayesian prior distributions are summarized in Table 4.

Table 4: A summary of estimated model parameters, lower bound, upper bound, type of prior, (U, uniform; N, normal; LN = lognormal), mean and CV of the prior.

Parameter	Phase	Prior	μ	CV	Lower	Upper
$\ln(R_0)$	1	U	–	–	5	50
M (natural mortality)	3	U	–	–	0.01	0.5
g_1 (Mean growth at 75 mm)	2	U	–	–	0.01	150
g_2 (Mean growth at 120 mm)	2	U	–	–	0.01	150
g_{50}	2	U	–	–	0.01	150
$g_{50-95\%}$	2	U	–	–	0.01	150
g_{max}	1	U	–	–	0.01	50
α	2	U	–	–	0.01	10
β	2	U	–	–	0.01	10
$\ln(q^I)$ (catchability coefficient of CPUE)	1	U	–	–	-30	0
$\ln(q^J)$ (catchability coefficient of PCPUE)	1	U	–	–	-30	0
L_{50} (Length at 50% maturity)	1	U	–	–	70	145
L_{95-50} (Length between 50% and 95% maturity)	1	U	–	–	1	50
D_{50} (Length at 50% selectivity for the commercial catch)	2	U	–	–	70	145
D_{95-50} (Length between 50% and 95% selectivity for the commercial catch)	2	U	–	–	0.01	50
D_s	1	U	–	–	0.01	10
ϵ (Recruitment deviations)	1	N	0	0.4	-2.3	2.3

The observational data were:

1. A 1990–2001 standardised CPUE series based on CELR data.
2. A 2002–2017 standardised CPUE series based on PCELR data.
3. A commercial catch sampling length frequency series for 1998, 2002–04, 07, 2009–2012.
4. Tag-recapture length increment data.
5. Maturity at length data

4.1.1 Relative abundance estimates from standardised CPUE analyses

The 2017 stock assessment used two sets of standardised CPUE indices: one based on CELR data covering 1990–2001, and another based on PCELR data covering 2002–2017. For both series, standardised CPUE analyses were carried out using Generalised Linear Models (GLMs). A stepwise procedure was used to select predictor variables, with variables entering the model in the order that gave the maximum decrease in the residual deviance. Predictor variables were accepted in the model only if they explained at least 1% of the deviance.

For both the CELR and PCELR data, the Fisher Identification Number (FIN) was used in the standardisations instead of vessel, because the FIN is associated with a permit holder who may employ a suite of grouped vessels, which implies that there could be linkage in the catch rates among vessels operated under a single FIN.

For the CELR data (1990–2001) there is ambiguity in what is recorded for estimated daily fishing duration (total fishing duration for all divers), and it has not been used in past standardisations as a measure of effort; instead the number of divers has been used. However, there is evidence that the fishing duration for a diver changes over time, and because of this criteria were used to identify records for which the recorded fishing duration should predominantly be recorded correctly. The criteria used to subset the data were: (i) just one diver or (ii) fishing duration ≥ 8 hours and number of divers ≥ 2 . For the other records the recorded fishing duration was multiplied by the number of diver. The data set consisting of predominantly correct records for the recorded fishing duration, and others with the recorded fishing duration scaled up by the number of divers was used for the CELR standardisation using estimated daily catch and effort as estimated fishing duration.

For the PCELR data (2002–2017) the unit of catch was diver catch, with effort as diver duration.

FIN codes were used to select a core group of fishers from the CELR data, with the requirement that there be a minimum of 7 records per year for a minimum of 2 years to qualify for the core fisher group. This retained 84% of the catch over 1990–2001. For the PCELR data the FIN was also used to select a core group of fishers, with the requirement that there be a minimum of 20 records per year for a minimum of 3 years. This retained 87% of the catch over 2002–2017.

For the CELR data, year was forced into the model and other predictor variables offered to the model were FIN, Statistical Area (025, 027, 029, 030), month and fishing duration (as a cubic polynomial). For the PCELR data, fishing year was forced into the model and variables offered to the model were month, diver key, FIN statistical area, diver duration (third degree polynomial), and diving conditions.

The standardised CPUE from the CELR data shows an increase from 1990 to 1991 followed by a steady decline through to 2001 at which point it is 49% of its initial 1990 level (Figure 3-top). The standardised CPUE from the PCELR data shows a 74% increase from 2002 to 2014 then a slight decline from 2014 to 2017. This 13% decline between 2014 and 2017 is not unexpected and is most likely due to the commercial fishers voluntarily increasing the minimum harvest size (Figure 3-bottom).

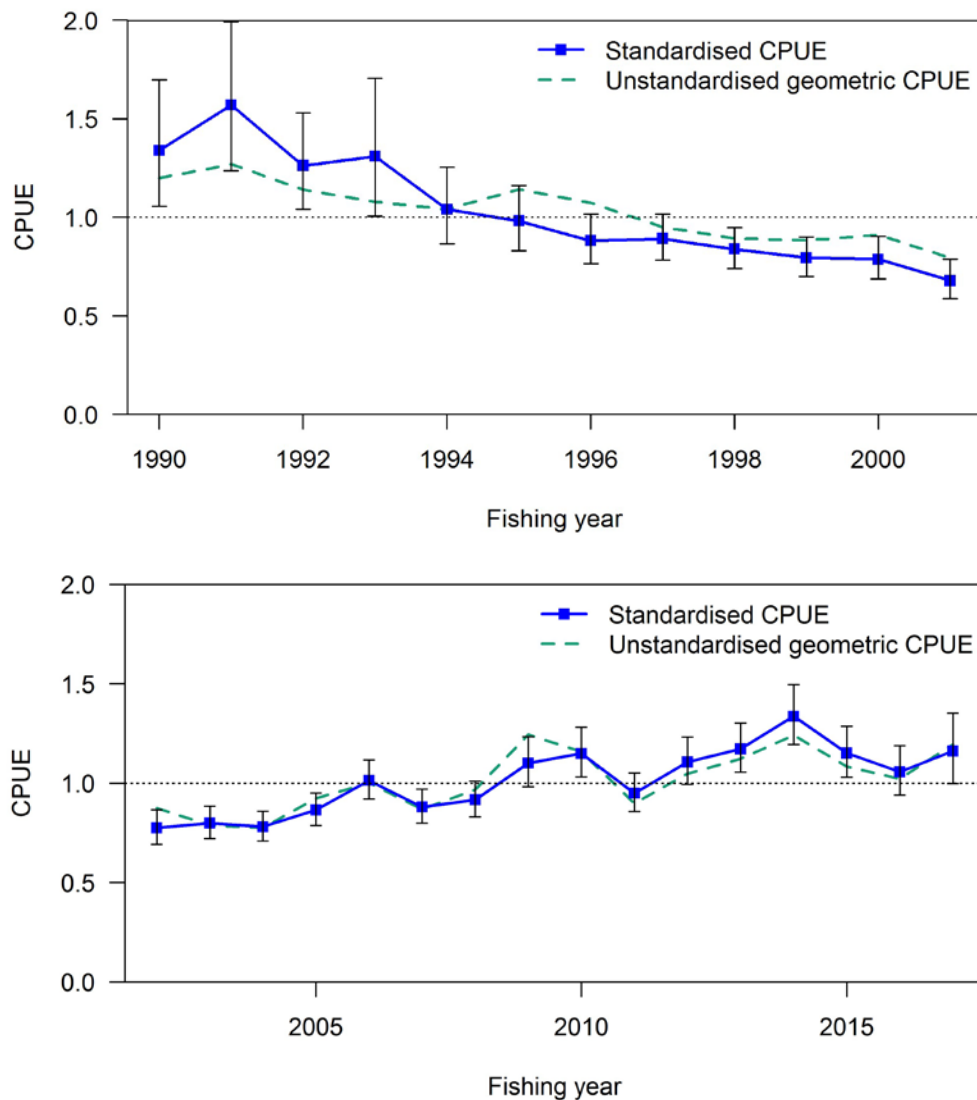

Figure 3: The standardised CPUE indices with 95% confidence intervals for the CELR series covering 1990–2001 (blue line for top-figure). The standardised CPUE indices with 95% confidence intervals for the PCELR series covering 2002–2017 (blue line for bottom-figure). For both indices the unstandardised geometric CPUE is calculated as catch divided by fishing duration.

4.1.2 Relative abundance estimates from research diver surveys

The relative abundance of paua in PAU 5B has also been estimated from a number of independent research diver surveys (RDSI) undertaken in various years between 1993 and 2007. The survey strata included Ruggedy, Waituna, Codfish, Pegasus, Lords, and East Cape. These data were included in the assessment although there is concern that the data are not a reliable index of abundance.

Concerns about the ability of the data collected in the independent Research Dive surveys to reflect relative abundance instigated several reviews in 2009 (Cordue 2009) and 2010 (Haist 2010). The reviews assessed the reliability of the research diver survey index as an index of abundance and whether the RDSI, when used in the paua stock assessment models, results in model outputs that adequately reflect the status of the stocks. Both reviews suggested that outputs from paua stock assessments using the RDSI should be treated with caution however this data was included in the 2017 assessment based on recommendations arising from the paua stock assessment review workshop (Butterworth et al 2015).

4.2 Stock assessment methods

The 2017 PAU 5B stock assessment used the same length-based model as the 2017 PAU 5D assessment (Marsh & Fu 2017). The model was described by Breen et al (2003). PAU 5B was last assessed in 2013 (Fu 2014 and Fu et al 2014a).

The model structure assumed a single sex population residing in a single homogeneous area, with length classes from 70 mm to 170 mm in 2 mm bins. Growth is length-based, without reference to age, mediated through a growth transition matrix that describes the probability of transitions among length class at each time step. Paua enter the model following recruitment and are removed by natural mortality and fishing mortality.

The model simulates the population from 1965 to 2017. Catches were available for 1974–2017 although catches before 1995 must be estimated from the combined PAU 5 catch. Catches were assumed to increase linearly between 1965 and 1973 from 0 to the 1974 catch level. Catches included commercial, recreational, customary, and illegal catch, and all catches occurred within the same time step.

Recruitment was assumed to take place at the beginning of the annual cycle, and length at recruitment was defined by a uniform distribution with a range between 70 and 80 mm. No explicit stock-recruitment relationship was modelled in previous assessments; however, the Shellfish Working Group agreed to use a Beverton-Holt stock-recruitment relationship with steepness (h) of 0.75 for this assessment.

Maturity is not required in the population partition but is necessary for estimating spawning biomass. The model estimated proportions mature from length-at-maturity data. Growth and natural mortalities were also estimated within the model. The model estimated the commercial fishing selectivity, assumed to follow a logistic curve and asymptote at 1. The increase in Minimum Harvest Size between 2006 and 2017 was modelled as an annual shift in fishing selectivity.

The assessment was conducted in several steps. First, the model was fitted to the data with parameters estimated at the mode of their joint posterior distribution (MPD). Next, from the resulting fit, Markov chain-Monte Carlo (MCMC) simulations were made to obtain a large set of samples from the joint posterior distribution. From this set of samples, forward projections were made and an agreed set of biological indicators obtained. Model sensitivity was explored by comparing MPD fits made under alternative model assumptions.

The base case incorporated a number of changes since the last assessment of PAU 5B in 2013. First, a more flexible functional form (inverse logistic) was used to describe the variance associated with the mean growth increment at length. Second, the predicted CPUE is now calculated after 50% of the fishing and natural mortality have occurred (previously the CPUE indices were fitted to the vulnerable biomass calculated after 50% of the catch was taken). This is considered to be appropriate if fishing occurs throughout a year (Schnute 1985). The change was recommended by the paua review workshop held in Wellington in March 2015 (Butterworth et al. 2015). Accordingly, mid-season numbers (and biomass) was calculated after half of the natural mortality and half of the fishing mortality was applied.

The third change was made to the likelihood function, fitting the tag-recapture observations so that weights could be assigned to individual data sets. This also followed the paua review workshop's recommendation that "the tagging data should be weighted by the relative contribution of average yield from the different areas so that the estimates could better reflect the growth rates from the more productive areas" (Butterworth et al 2015). Two smaller changes were added in this iteration of the assessment model, including: 1) adding a lag between recruitment and spawning for models where the partition was started at > 2 mm; and 2) adding a time varying parameter on the catchability coefficient of the CPUE observations.

The base case model (0.1) and the six sensitivities (0.1all and 0.2–0.6) were considered (Table 5): two separate CPUE series (0.2), excluding research diver observations (0.3), alternative catch history (0.4), modelling the partition at 2 mm (0.5), and estimating a time varying catchability (0.6). MCMCs were carried out for the base case and model runs 0.4 and 0.6.

Table 5: Summary descriptions of base case (0.1) and sensitivity model runs.

Model	Description
0.1	inverse logistic growth model, tag-recapture weighted, CSLF data up to 2016, M prior Uniform, tag data > 70 mm, RDLF and RDSI included, Combined CPUE series, Catch history assumption 3
0.1 all	The same as model 0.1 with CSLF data up to and including the 2017 fishing year.
0.2	Model 0.1 with split CPUE series, one for the CELR and another for the PCELR
0.3	Model 0.1 but with the RDLF and RDSI data excluded
0.4	Model 0.1 but with catch history assumption 1
0.5	Model 0.1 but start modelling at 2 mm instead of 70 mm
0.6	Model 0.1 but with a time varying catchability coefficient, with an estimated drift parameter $\sim \text{Uniform}(-0.05, 0.05)$

The assessment calculated the following quantities from their posterior distributions: the equilibrium spawning stock biomass with recruitment equal to the average recruitment from the period for which recruitment deviation were estimated (B_0), the mid-season spawning and recruited biomass for 2013 (B_{2013} and B_{2013}^r) and for the projection period (B_{proj} and B_{proj}^r). This assessment also reported the following fishery indicators:

- $B\% B_0$ Current or projected spawning biomass as a percentage of B_0
- $B\% B_{msy}$ Current or projected spawning biomass as a percentage of B_{msy}
- $\Pr(B_{proj} > B_{msy})$ Probability that projected spawning biomass is greater than B_{msy}
- $\Pr(B_{proj} > B_{2012})$ Probability that projected spawning biomass is greater than $B_{current}$
- $B\% B_0^r$ Current or projected recruited biomass as a percentage of B_0^r
- $B\% B_{msy}^r$ Current or projected recruited biomass as a percentage of B_{msy}^r
- $\Pr(B_{proj} > B_{msy}^r)$ Probability that projected recruit-sized biomass is greater than B_{msy}^r
- $\Pr(B_{proj} > B_{2012}^r)$ Probability that projected recruit-sized biomass is greater than B_{2012}^r
- $\Pr(B_{proj} > 40\% B_0)$ Probability that projected spawning biomass is greater than 40% B_0
- $\Pr(B_{proj} < 20\% B_0)$ Probability that projected spawning biomass is less than 20% B_0
- $\Pr(B_{proj} < 10\% B_0)$ Probability that projected spawning biomass is less than 10% B_0
- $\Pr(U_{proj} > U_{40\% B_0})$ Probability that projected exploitation rate is greater than $U_{40\% B_0}$

4.3 Stock assessment results

The base case model (0.1) estimated that the unfished spawning stock biomass (B_0) was about 3948 t (3630–4271 t) (Figure 4), and the spawning stock population in 2017 (B_{2017}) was about 47% (39–58%) of B_0 (Table 6). The base case indicated that spawning biomass increased rapidly after 2002 when the stock was at its lowest level.

Three-year projections (2018–2020) were run for two alternative recruitment assumptions, with the period of recruitment sampled from the past 10 years of estimates and from the past 5 years of estimates (explored due to recent lower-than-average recruitment), and with four different future harvest levels based on changes to the total allowable catch (TACC), with the TACC increasing by 5% (94.5 t), 10% (99 t), 15% (103.5 t) and 20% (108 t) (Tables 7–10). The base case model suggested that the current stock status was very unlikely to fall below the target of 40% B_0 . The projections suggested that with an increase of 20% of the current TACC, future biomass was likely to remain constant over the next 3 years. The conclusion was similar across all sensitivity runs.

The MCMC simulation started at the MPD parameter values and the traces show good mixing. MCMC chains starting at either higher or lower parameter values also converged after the initial burn-in phase. The base case model estimated an M of 0.10 with a 90% credible interval between 0.08 and 0.12. The midpoint of the commercial fishery selectivity (pre-2006), where selectivity is 50% of the maximum, was estimated to be about 125 mm and the selectivity ogive was very steep. The model estimated an annual shift of about 1.9 mm in selectivity, with a total increase of about 10 mm between 2006 and 2011.

The estimated recruitment deviations showed a period of relatively low recruitment through the 1990s to the early 2000s. From the early 2000s to 2010 recruitment was above the average however, from 2011 until 2015 recruitment has been lower than the long-term average. (Figure 5). Exploitation rates peaked around 2002, but have decreased since then. The base case estimated exploitation rate in 2017 to be about 0.09 (0.07–0.11) (Table 6).

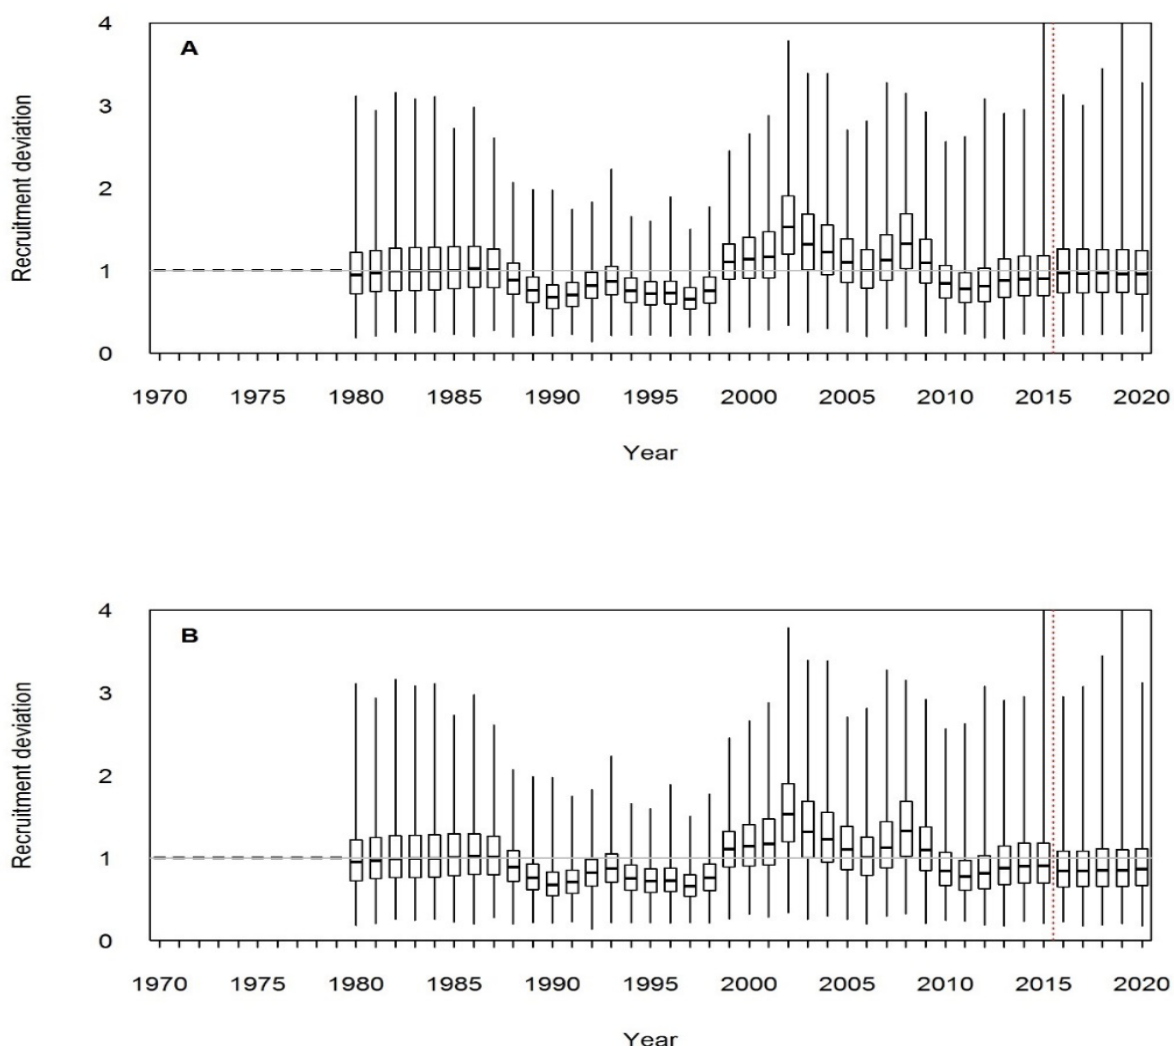

Figure 4: Recruitment deviations around the stock recruitment relationship estimated and forecasted for model 0.1. The red line is the time up to where recruitment deviations were resampled from. The top figure (A) is when we resample from the last 10 years. The bottom figure (B) is when we resample from the last 5 years.

Table 5: Summary of the marginal posterior distributions from the MCMC chain from the base case (Model 0.1), and the sensitivity trials (models 0.4 and 0.6). The columns show the median, the 5th and 95th percentiles values observed in the 1000 samples. Biomass is in tonnes.

4.4 Other factors

The assessment used CPUE as an index of abundance. The assumption that CPUE indexes abundance is questionable. The literature on abalone fisheries suggests that CPUE is problematic for stock assessments because of serial depletion. This can happen when fishers deplete unfished or lightly fished beds and maintain their catch rates by moving to new areas. Thus CPUE stays high while the biomass is actually decreasing. For PAU 5B, the model estimate of stock status was strongly driven by the trend in the recent CPUE indices. It is unknown to what extent the CPUE series tracks stock abundance. The SFWG believed that the increasing trend in recent CPUE series are credible, corroborating anecdotal evidence from the commercial divers in PAU 5B that the stock has been in good shape in recent years.

Natural mortality is an important productivity parameter. It is often difficult to estimate M reliably within a stock assessment model and the estimate is strongly influenced by the assumed prior. For the paua assessment, the choice of prior has been based on current belief on the plausible range of the natural mortality for paua, and therefore it is reasonable to incorporate available evidence to inform the estimation of M . The sensitivity of model results to the assumptions on M could be assessed through the use of alternative priors.

Another source of uncertainty is the data. The commercial catch is unknown before 1974 and is estimated with uncertainty before 1995. Major differences may exist between the catches we assume and what was actually taken. In addition, non-commercial catch estimates are poorly determined and could be substantially different from what was assumed, although generally non-commercial catches appear to be relatively small compared with commercial catch. The estimate of illegal catch in particular is uncertain.

The model treats the whole of the assessed area of PAU 5B as if it were a single stock with homogeneous biology, habitat and fishing pressures. The model assumes homogeneity in recruitment and natural mortality, and assumes that growth has the same mean and variance throughout. Heterogeneity in growth can be a problem for this kind of model (Punt 2003). Variation in growth is addressed to some extent by having a stochastic growth transition matrix based on increments observed in several different places; similarly the length frequency data are integrated across samples from many places.

The effect of these factors is likely to make model results optimistic. For instance, if some local stocks are fished very hard and others not fished, recruitment failure can result because of the localized depletion of spawners. Spawners must be close to each other to breed and the dispersal of larvae is unknown and may be limited. Recruitment failure is a common observation in overseas abalone fisheries, so local processes may decrease recruitment, an effect that the current model cannot account for.

Another source of uncertainty is that fishing may cause spatial contraction of populations (Shepherd & Partington 1995), or that some populations become relatively unproductive after initial fishing (Gorfine & Dixon 2000). If this happens, the model will overestimate productivity in the population as a whole. Past recruitments estimated by the model might instead have been the result of serial depletion.

4.5 Future research considerations

- Continue to develop fisheries-independent survey methodologies that are representative of the PAU 5B area;
- Further investigate q -drift to determine how to quantify it and its implications for assessment outcomes;
- Ensure models are robust to assumptions about, or estimates of, natural mortality and stock-recruitment parameters;
- Review the commercial catch sampling programme in light of the increasing trend of live or frozen-in-shell exports.

5. STATUS OF THE STOCK

Stock Structure Assumptions

PAU 5B is assumed to be a homogenous stock for purposes of the stock assessment.

- **PAU 5B - *Haliotis iris***

Stock Status	
Year of Most Recent Assessment	2018
Assessment Runs Presented	MCMC 0.1 (base case)
Reference Points	Target: 40% B_0 (Default as per HSS) Soft Limit: 20% B_0 (Default as per HSS) Hard Limit: 10% B_0 (Default as per HSS) Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	B_{2017} was estimated to be 47% B_0 for the base case; Likely (> 60%) to be at or above the target
Status in relation to Limits	Very Unlikely (< 10%) to be below the soft and hard limits
Status in Relation to Overfishing	Overfishing is Very Unlikely (< 10%) to be occurring
Historical Stock Status Trajectory and Current Status	
<p style="text-align: center;">MCMC 0.1</p> <p>Posterior distributions of spawning stock biomass as a percentage of the unfished level from MCMC 0.1. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.</p>	

Trajectory of exploitation rate as a ratio $U_{40\%B_0}$ and spawning stock biomass as a ratio of B_0 from the start of assessment period 1965 to 2017 for MCMC 0.1 (base case). The vertical lines at 10%, 20% and 40% B_0 represent the hard limit, the soft limit, and the target respectively. $U_{40\%B_0}$ is the exploitation rate at which the spawning stock biomass would stabilise at 40% B_0 over the long term. Each point on trajectory represents the estimated annual stock status: the value on x axis is the mid-season spawning stock biomass (as a ratio of B_0) and the value on the y axis is the corresponding exploitation rate (as a ratio $U_{40\%B_0}$) for that year. The estimates are based on MCMC medians and the 2017 90% CI is shown by the crossed line.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass decreased to its lowest level in 2002 but has increased since then.
Recent Trend in Fishing Intensity or Proxy	Exploitation rate peaked in late 1990s and has since declined.
Other Abundance Indices	Standardised CPUE generally declined until the early 2000s, but has shown an overall increase since then.
Trends in Other Relevant Indicators or Variables	Estimated recruitment was relatively low through the 1990s to the early 2000s, increased from 2002 until 2010 and has since fallen below the long term average.

Projections and Prognosis

Stock Projections or Prognosis	At the current catch level biomass is expected to remain at or above the target over the next 3 years.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Results from all models suggest it is Very Unlikely (< 10%) that current catch or TACC will cause a decline below the limits.
Probability of Current Catch or TACC to cause Overfishing to continue or to commence	Very Unlikely (< 10%)

Assessment Methodology and Evaluation

Assessment Type	Full Quantitative Stock Assessment	
Assessment Method	Length-based Bayesian model	
Assessment Dates	Latest: 2018	Next: 2021
Overall assessment quality (rank)	1 – High Quality	
Main data inputs (rank)	- Catch history	1 – High Quality for commercial

	<ul style="list-style-type: none"> - CPUE indices early series - CPUE indices later series - Commercial sampling length frequencies - Tag recapture data (for growth estimation) - Maturity at length data - Research Dive Survey Indices 	<p>catch</p> <p>2 – Medium or Mixed Quality for recreational, customary and illegal as catch histories are not believed to be fully representative of the QMA</p> <p>2 – Medium or Mixed Quality: not believed to be fully representative of the whole QMA</p> <p>1 – High Quality</p> <p>2 – Medium or Mixed Quality: not believed to be fully representative of the whole QMA</p> <p>1 – High Quality</p> <p>1 – High Quality</p> <p>2 – Medium or Mixed Quality: uncertain whether it indexes the stock</p>
Data not used (rank)	- Research Dive Length Frequencies	2 – Medium or Mixed Quality: not believed to be representative of the entire QMA
Changes to Model Structure and Assumptions	New model	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - M may not be estimated accurately. - CPUE may not be a reliable index of abundance and it is unclear whether catchability has changed over time. - The model treats the whole of the assessed area of PAU 5B as if it were a single stock with homogeneous biology, habitat and fishing pressure. - Any effect of voluntary increases in MHS from 125 mm to 137 mm between 2006 and 2017 may not have been adequately captured by the model, which could therefore be underestimating the spawning biomass in recent years.

PAUA (PAU 5D) - Southland / Otago

(*Haliotis iris*)

Pāua

1. FISHERY SUMMARY

Before 1995, PAU 5D was part of the PAU 5 QMA, which was introduced into the QMS in 1986 with a TACC of 445 t. As a result of appeals to the Quota Appeal Authority, the TACC increased to 492 t for the 1991–92 fishing year; PAU 5 was then the largest QMA by number of quota holders and TACC. Concerns about the status of the PAU 5 stock led to a voluntary 10% reduction in the TACC in 1994–95. On 1 October 1995, PAU 5 was divided into three QMAs (PAU 5A, PAU 5B, and PAU 5D; see figure above) and the TACC was divided equally among them; the PAU 5D quota was set at 148.98 t.

On 1 October 2002 a TAC of 159 t was set for PAU 5D, comprising a TACC of 114 t, customary and recreational allowances of 3 t and 22 t respectively, and an allowance of 20 t for other mortality. The TAC and TACC have been changed since then but customary, recreational and other mortality allowances have remained unchanged (Table 1).

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 5 and PAU 5D since introduction to the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–1991*	-	-	-	-	445
1991–1994*	-	-	-	-	492
1994–1995*	-	-	-	-	442.8
1995–2002	-	-	-	-	148.98
2002–2003	159	3	22	20	114
2003–present	134	3	22	20	89

*PAU 5 TACC figures

1.1 Commercial fishery

The fishing year runs from 1 October to 30 September. On 1 October 2001, it became mandatory to report catch and effort on Paua Catch Effort Landing Return (PCELR) forms using fine-scale reporting areas that had been developed by the New Zealand Paua Management Company for their

PAUA (PAU 5D)

voluntary logbook programme (Figure 1). Since 2010, the commercial industry has adopted some voluntary management initiatives which include raising the minimum harvest size for commercial fishers over specific statistical reporting areas. The industry has also voluntarily closed, to commercial harvesting, specific areas that are of high importance to recreational paua fishers. For the past three years commercial fishers have been voluntarily shelving a percentage of their Annual Catch Entitlement (ACE), which is reflected by the annual catch landings falling below the TACC (Figure 2, Table 2).

Figure 1: Map of fine scale statistical reporting areas for PAU 5D.

Commercial landings for PAU 5D are shown in Table 2 and Figure 2. Commercial landings for PAU 5 are reported in the introductory PAU Working Group Report.

Table 2: TACC and reported landings (t) of paua in PAU 5D from 1995–96 to the present. Data were estimated from CELR and QMR returns.

Year	Landings	TACC
1995–96	167.42	148.98
1996–97	146.6	148.98
1997–98	146.99	148.98
1998–99	148.78	148.98
1999–00	147.66	148.98
2000–01	149.00	148.98
2001–02	148.74	148.98
2002–03	111.69	114.00
2003–04	88.02	89.00
2004–05	88.82	89.00
2005–06	88.93	89.00
2006–07	88.97	89.00

Table 2 [Continued]

Year	Landings	TACC
2007–08	88.98	89.00
2008–09	88.77	89.00
2009–10	89.45	89.00
2010–11	88.70	89.00
2011–12	89.23	89.00
2012–13	87.91	89.00
2013–14	84.59	89.00
2014–15	71.87	89.00
2015–16	65.95	89.00
2016–17	63.12	89.00

Figure 2: Reported commercial landings and TACC for PAU 5D from 1995–96 to present. For reported commercial landings in PAU 5 prior to 1995–96 refer to figure 1 and table 1 of the introductory PAU Working Group Report.

1.2 Recreational fisheries

For the purpose of the stock assessment model, the SFWG agreed to assume that the recreational catch in 1974 was 2 t and that it increased linearly to 10 t by 2005, where it has remained unchanged to date. For further information on recreational fisheries refer to the introductory PAU Working Group Report.

1.3 Customary fisheries

For the purpose of the stock assessment model, the SFWG agreed to assume that, for PAU 5D, the customary catch has been constant at 2 t from 1974 to the current stock assessment. For further information on customary fisheries refer to the introductory PAU Working Group Report.

1.4 Illegal catch

For the purpose of the stock assessment model, the SFWG agreed to assume that, for PAU 5D, illegal catches have been constant at 10 t from 1974 to the current stock assessment. For further information on illegal catch refer to the introductory PAU Working Group Report.

1.5 Other sources of mortality

For further information on other sources of mortality refer to the introductory PAU Working Group Report.

2. BIOLOGY

For further information on paua biology refer to the introductory PAU Working Group Report. A summary of biological parameters used in the PAU 5D assessment is presented in Table 3.

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Working Group Report.

Table 3: Estimates of biological parameters (*H. iris*).

	Estimate	Source
1. Natural mortality (<i>M</i>)	0.14(0.12-0.16)	Median (5–95% range) of posterior estimated by the base case model
2. Weight = $a(\text{length})^b$ (Weight in g, length in mm shell length)		
All	a b	
	2.99 x 10 ⁻⁵ 3.303	Schiel & Breen (1991)
3. Size at maturity (shell length)		
50% maturity at 84 mm (83–85)		Median (5–95% range) of posterior estimated by the base case model
95% maturity at 101 mm (103–106)		Median (5–95% range) of posterior estimated by the base case model
4. Estimated annual growth increments (both sexes combined)		
at 75 mm	at 120 mm	Median (5–95% range) of posteriors estimated by the base case model
28.8 (26.0–31.9)	6.8(6.3–7.2)	

4. STOCK ASSESSMENT

The stock assessment was implemented as a length-based Bayesian estimation model, with point estimates of parameters based on the mode of the joint posterior distribution, and uncertainty of model estimates investigated using the marginal posterior distributions generated from Markov chain-Monte Carlo simulations. The most recent stock assessment was conducted for the fishing year ended 30 September 2016. A base case model (0.0 - referred to as the reference model henceforth) was chosen from the assessment. However, some data sets used in the model were from a limited number of locations and were most likely not representative of the whole QMA. Components of the stock assessment model that had the greatest uncertainty were the choice of mean and variance parameters on the prior of natural mortality (*M*), uncertainty associated with CPUE, and the proportionality assumption associated with CPUE and expected biomass.

4.1 Estimates of fishery parameters and abundance indices

Parameters estimated in the assessment model and their assumed Bayesian priors are summarized in Table 4.

Table 4: A summary of estimated model parameters, lower bound, upper bound, type of prior, (U, uniform; N, normal; LN = lognormal), mean and CV of the prior.

Parameter	Prior	μ	CV	Bounds	
				Lower	Upper
$\ln(R0)$	U	–	–	5	50
<i>M</i> (Natural mortality)	LN	0.1	0.1	0.01	0.5
g_1 (Mean growth at 75 mm)	U	–	–	1	50
g_2 (Mean growth at 120 mm)	U	–	–	0.01	50
ϕ (CV of mean growth)	U	–	–	0.001	1
$\ln(q^I)$ (catchability coefficient of CPUE)	U	–	–	-30	0
$\ln(q^I)$ (catchability coefficient of PCPUE)	U	–	–	-30	0
L_{50} (Length at 50% maturity)	U	–	–	70	145
L_{95-50} (Length between 50% and 95% maturity)	U	–	–	1	50
D_{50} (Length at 50% selectivity for the commercial catch)	U	–	–	70	145
D_{95-50} (Length between 50% and 95% selectivity the commercial catch)	U	–	–	0.01	50
ϵ (Recruitment deviations)	N	0	0.4	-2.3	2.3

The observational data were:

1. A standardised CPUE series covering 1990–2001 based on CELR data.
2. A standardised CPUE series covering 2002–2016 based on PCELR data.
3. A commercial catch sampling length frequency series for 1998, 2002–04, 07, 2009–2015.
4. Tag-recapture length increment data.
5. Maturity at length data

4.1.1 Relative abundance estimates from standardised CPUE analyses

The 2016 stock assessment used two sets of standardised CPUE indices: one based on CELR data covering 1990–2001, and another based on PCELR data covering 2002–2016. For both series, standardised CPUE analyses were carried out using Generalised Linear Models (GLMs). A stepwise procedure was used to select predictor variables, and they were entered into the model in the order that gave the maximum decrease in the Akaike Information Criterion (AIC). Predictor variables were accepted into the model only if they explained at least 1% of the deviance.

For the CELR data, there is ambiguity in what is recorded for estimated daily fishing duration: either incorrectly recorded as hours per diver, or correctly as total hours for all divers. For PAU 5D, fishing duration appeared to have been predominantly recorded as hours per diver. The standardisation was therefore restricted to records where fishing duration was ≤ 10 hours. Another subset was applied where only a core group of records were selected based on the following criteria. Divers with a minimum of 5 records per year for a minimum of 4 years. Applying these criteria to the CELR data retained 82% of the catch over 1990–2001.

CELR CPUE was defined as daily catch, with year forced into the model at the start. Other predictor variables offered to the model were FIN (Fisher Identification Number), Statistical Area (024, 025, 026, 030), month, and total fishing duration (as a cubic polynomial). Total fishing duration is the recorded fishing duration multiplied by the number of divers for a record (recall fishing duration is incorrectly recorded as the diving duration per diver). The model explained 69% of the variability in CPUE with fishing duration (53%) explaining most of this followed by FIN (13%). The CELR data showed an overall stable to slight decline in CPUE from 1990 through to the early 2000s (Figure 3, upper panel).

For the PCELR data the following criteria was used to subset out a core group of records. The criteria of a minimum of 20 records per year for a minimum of 4 years was chosen. Applying these criteria retained 84% of the catch over 2002–2016. The dependent variable was modelled as log (diver catch) with a normal error distribution. Fishing year was forced into the model at the start. Variables offered to the model were month, diver key, FIN, statistical area, duration (third degree polynomial), and diving condition. Following previous standardisations, no interaction of fishing year with area was entered into the model, because the stock assessment for PAU 5D is a single area model. Except for FIN, all variables were accepted into the model, which explained 74% of the variability in CPUE. Most of the variability was explained by duration (55%) and diver (7%). The standardised index shows an increase from 2002 to 2011, then a decline after this (Figure 3, lower panel). There is little difference between the unstandardised and standardised CPUE, with most of the difference attributable to the fishing duration predictor.

In some circumstances, commercial CPUE may not be proportional to abundance because it is possible to maintain catch rates of paua despite a declining biomass. This occurs because paua tend to aggregate and divers move among areas to maximise their catch rates. Apparent stability in CPUE should therefore be interpreted with caution, the assumption of CPUE being proportional to biomass was investigated using the assessment model.

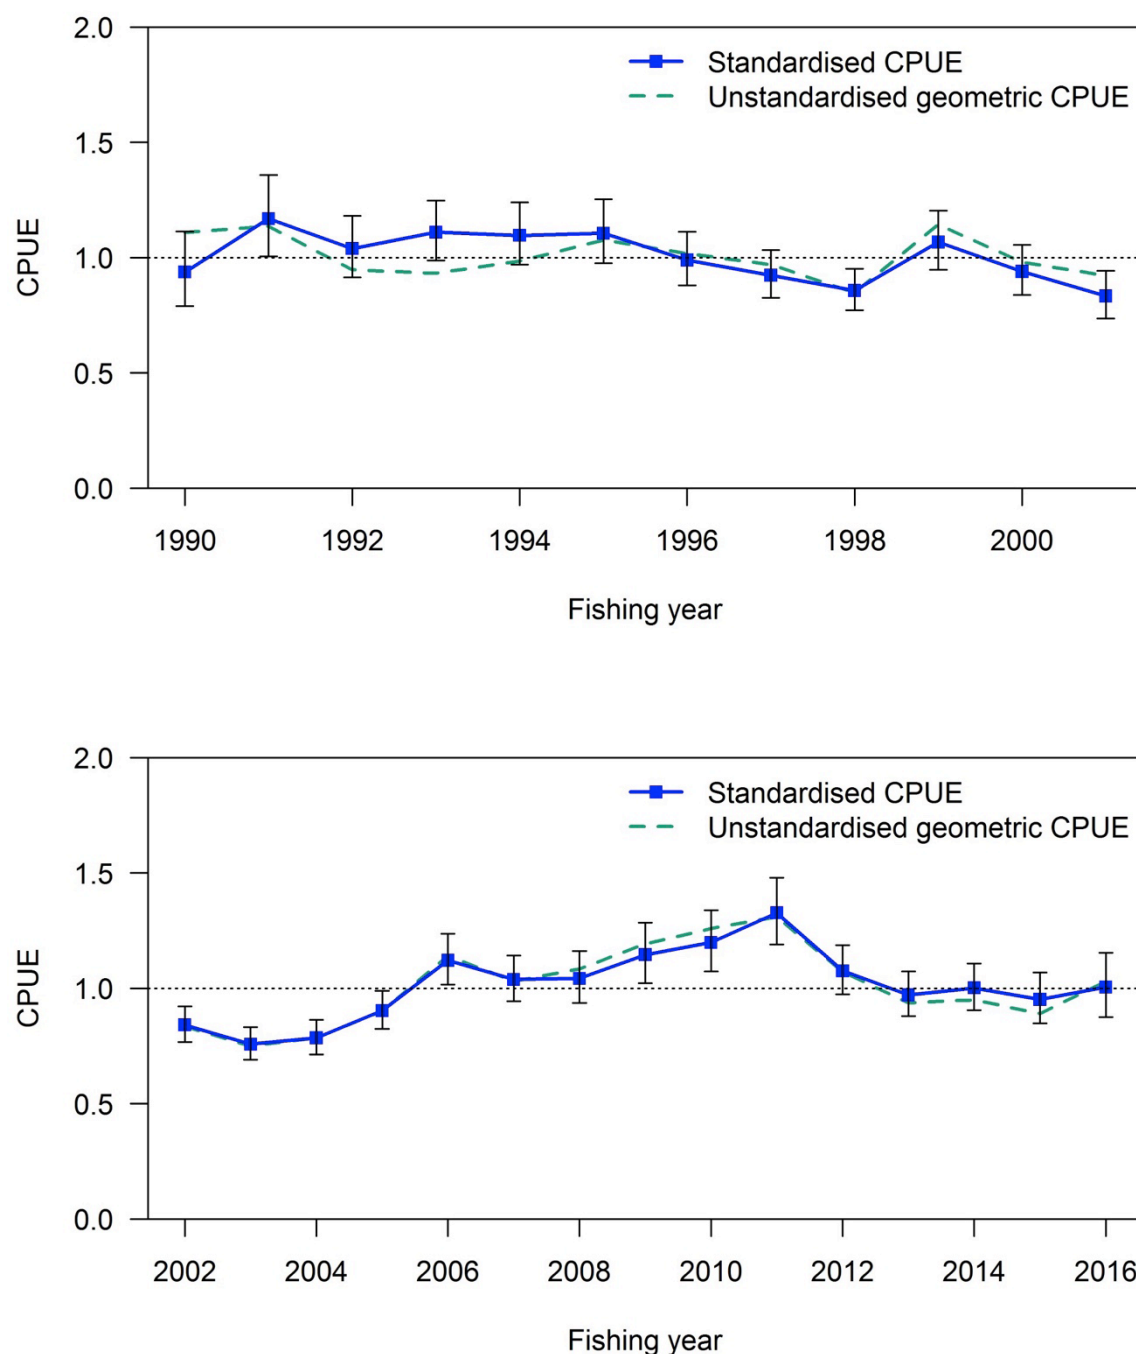

Figure 3: The standardised CPUE indices with 95% confidence intervals and unstandardized geometric CPUE for the early CELR series (upper panel) and the recent PCELR series (lower panel).

4.1.2 Relative abundance estimates from research diver surveys

The relative abundance of puaa in PAU 5D has also been estimated from a number of independent research diver surveys (RDSI) undertaken in various years between 1994 and 2004. The survey strata (Catlins East and Catlins West) cover the areas that produced about 25% of the recent catches in PAU 5D. This data was not included in the assessment because there is concern that the data is not a reliable enough index of abundance and the data is not representative of the entire PAU 5D QMA.

Concerns about the ability of the data collected in the independent Research Dive surveys to reflect relative abundance instigated reviews in 2009 (Cordue 2009) and 2010 (Haist 2010). The reviews assessed the reliability of the research diver survey index as a proxy for abundance and whether the RDSI, when used in the puaa stock assessment models, results in model outputs that adequately reflect the status of the stocks. Both reviews suggested that outputs from puaa stock assessments

using the RDSI should be treated with caution. For a summary of the reviews conclusions refer to the introductory PAU Working Group Report

4.2 Stock assessment methods

The 2016 PAU 5D stock assessment used the same length-based model used for the 2015 PAU 7 assessment (Fu 2016). The model was described by Breen et al (2003). PAU 5D was last assessed using data up to the 2011–2012 fishing year (Fu 2013), and the most recent assessment uses data up to the 2015–2016 fishing year (Marsh & Fu 2017). Changes to the stock assessment model between these two assessments include; 1) using a more flexible function form to describe the variance associated with the mean growth increment at length, 2) predicted CPUE was calculated after 50% of the fishing and natural mortality have occurred (previously the CPUE indices were fitted to the vulnerable biomass calculated after 50% of the catch was taken), and 3) changes to the likelihood function fitting the tag-recapture observations so that weights could be assigned to individual observations. These all follow suggestions from Butterworth et al (2015).

The model structure assumed a single sex population residing in a single homogeneous area, with length classes from 70 mm to 170 mm, in groups of 2 mm. Growth is length-based, without reference to age, mediated through a growth transition matrix that describes the probability of each length class changing in each year. Paua entered the partition following recruitment and were removed by natural mortality and fishing mortality.

The model simulates the population from 1965 to 2016. Catches were available for 1974–2016 although catches before 1995 must be estimated from the combined PAU 5 catch, and were assumed to increase linearly between 1965 and 1973 from 0 to the 1974 catch level. Catches included commercial, recreational, customary, and illegal catch, and all catches occurred within the same time step.

Recruitment was assumed to take place at the beginning of the annual cycle, and length at recruitment was defined by a uniform distribution with a range between 70 and 80 mm. The stock-recruitment relationship is unknown for paua. No explicit stock-recruitment relationship was modelled in previous assessments. However, the Shellfish Working Group agreed to use a Beverton-Holt stock-recruitment relationship with steepness (h) of 0.75 for this assessment.

Maturity is not required in the population partition but is necessary for estimating spawning biomass. The model estimated the proportions of mature individuals from length-at-maturity data. Growth and natural mortalities were also estimated within the model. The model estimated the commercial fishing selectivity, which was assumed to follow a logistic curve and to reach an asymptote.

The assessment was conducted in several steps. First, the model was fitted to the data with arbitrary weights on the various data sets. The weights were then iteratively adjusted to produce balanced residuals among the datasets where the standardised deviation of the normalised residuals was close to one for each dataset. The length frequency data were further down-weighted using the method TA1.8 described by Francis (2011). The fit obtained is the mode of the joint posterior distribution of parameters (MPD). Next, from the resulting fit, Markov chain-Monte Carlo (MCMC) simulations were made to obtain a large set of samples from the joint posterior distribution. From this set of samples, forward projections were made with a set of agreed indicators obtained. Sensitivity trials were explored by comparing MPD fits made with alternative model assumptions.

The reference model (0.0) excluded the RDSI and RDLF data, fitted the two CPUE series and the CSLF data, estimated growth parameters within the model using an exponential growth curve with estimated variance parameters α and β , and estimated M within the model.

The sensitivity trials carried out for the MCMC and used for projecting the stock included: run 0.0e, where both CPUE series had double the observation error (coefficient of variation) associated with them, and run 0.0h, where we assumed a hyper-stable relationship between stock biomass and CPUE. The sensitivity trials addressed uncertainties in CPUE.

The assessment calculates the following quantities from their posterior distributions: the equilibrium spawning stock biomass assuming that recruitment is equal to the average recruitment from the period for which recruitment deviation were estimated (B_0), and the mid-season spawning and recruited biomass for 2016 (B_{2016} and B_{2016}^r) and for the projection period (B_{proj} and B_{proj}^r). This assessment also reports the following fishery indicators:

$B\% B_0$	Current or projected spawning biomass as a percentage of B_0
$B\% B_{msy}$	Current or projected spawning biomass as a percentage of B_{msy}
$\Pr(B_{proj} > B_{msy})$	Probability that projected spawning biomass is greater than B_{msy}
$\Pr(B_{proj} > B_{2016})$	Probability that projected spawning biomass is greater than $B_{current}$
$B\% B_0^r$	Current or projected recruited biomass as a percentage of B_0^r
$B\% B_{msy}^r$	Current or projected recruited biomass as a percentage of B_{msy}^r
$\Pr(B_{proj} > B_{msy}^r)$	Probability that projected recruit-sized biomass is greater than B_{msy}^r
$\Pr(B_{proj} > B_{2016}^r)$	Probability that projected recruit-sized biomass is greater than B_{2016}^r
$\Pr(B_{proj} > 40\% B_0)$	Probability that projected spawning biomass is greater than 40% B_0
$\Pr(B_{proj} < 20\% B_0)$	Probability that projected spawning biomass is less than 20% B_0
$\Pr(B_{proj} < 10\% B_0)$	Probability that projected spawning biomass is less than 10% B_0
$\Pr(U_{proj} > U_{40\% B_0})$	Probability that projected exploitation rate is greater than $U_{40\% B_0}$
$B\% B_0$	Current or projected spawning biomass as a percentage of B_0
$B\% B_{msy}$	Current or projected spawning biomass as a percentage of B_{msy}
$\Pr(B_{proj} > B_{msy})$	Probability that projected spawning biomass is greater than B_{msy}
$\Pr(B_{proj} > B_{2016})$	Probability that projected spawning biomass is greater than $B_{current}$

4.3 Stock assessment results

The reference case model (0.0) estimated that the unfished spawning stock biomass (B_0) was about 2457 t (2270 – 2672 t) (Table 5), and the spawning stock population in 2016 (B_{2016}) was about 35% (28–43%) of B_0 (Figure 4). The model projections, using recruitment re-sampled from the recent model estimates and assuming current catch levels (status quo, 2015–16 catch), suggested that the spawning stock abundance will increase to about 38% (28–52%) of B_0 over the next three years (Table 6). The projection also indicated that the probability of the spawning stock biomass being above the target (40% B_0) will increase from about 14% in 2016 to 40% by 2019.

The reference case model appeared to fit most data well, and there is no obvious indication of lack of fit. Natural mortality was estimated to be about 0.14. Estimated commercial catch selectivity was very steep with the 50% selectivity (D_{50}) being close to 125 mm. The estimated recruitment was high in the early 2000s. The estimated exploitation rate peaked in 2002 and since then has been decreasing, with the U_{2016} estimated at 19% and the exploitation rate required to achieve the target of 40% B_0 ($U_{40\% B_0}$) over the long term was 21%.

When the observation error on the early CPUE series was doubled (Run 0.0e), the model estimated the unfished spawning stock biomass (B_0) to be about 2597 t (2393 – 2825 t) and showed a slightly steeper decline in biomass between 1990 and 2002 (Figure 4, middle panel). Estimated B_{2016} was about 32% (25–41%) of B_0 , current exploitation rate was 20% and $U_{40\% B_0}$ was 18% (Table 5). The model projections (Table 7) suggested an increase in biomass over the next three years, with a 23% probability of being above the target of 40% B_0 by 2019.

When the early CPUE series was assumed to have a hyper-stable relationship with biomass (Run 0.0h), the unfished spawning stock biomass (B_0) was estimated at 2 562 t (2 355 – 2 775 t) (Figure 4, lower panel). B_{2016} was 28% (22–37%) of B_0 , U_{2016} was 23% and $U_{40\%B_0}$ was 17% (Table 5). The model projections (Table 8) suggested an increase in biomass over the next three years, with a 12% probability of being above the target by 2015.

Deterministic B_{msy} was also calculated in the 2016 assessment with B_{msy} estimated at 703 t, 747 t and 738 t for the 0.0, 0.0e and 0.0h assessment runs respectively (Table 5). The corresponding exploitation rates (U_{msy}) were estimated at 38%, 32% and 30% (Table 5). Projections from the different assessment runs, with probability statements on current and future stock status are displayed in Tables 6, 7 and 8.

For a number of reasons (as outlined below) B_{msy} is not currently used as a reference point for managing paua stocks. However, because determining the most suitable target and limit reference points for managing paua stocks is still work in progress B_{msy} is among the indicators that are being estimated.

There are several reasons why B_{msy} is not considered a suitable target for management of the paua fishery. Firstly, it assumes a harvest strategy that is unrealistic in that it involves perfect knowledge of catch and biology and perfect stock assessments (because current biomass must be known exactly in order to calculate target catch), a constant-exploitation management strategy with annual changes in TACC (which are unlikely to happen in New Zealand and not desirable for most stakeholders), and perfect management implementation of the TACC and catch splits with no under or over runs. Secondly, it assumes perfect knowledge of the stock-recruit relationship, which is actually very poorly known. Thirdly, it would be very difficult with such a low biomass target to avoid the biomass occasionally falling below 20% B_0 , the default soft limit according to the Harvest Strategy Standard. Thus, the actual target needs to be above this theoretical optimum; but the extent to which it needs to be above has not been determined.

Table 5: Summary of the marginal posterior distributions from the MCMC chain from Run 5.2 (base case), and sensitivity trials Run 5.5 (no early CPUE), 6.3 (fast growth), and 6.5 (slow growth). The columns show the median, the 5th and 95th percentiles values observed in the 1000 samples. Biomass is in tonnes.

4.4 Other factors

To run the stock assessment model a number of assumptions must be made, one of these being that CPUE is a reliable index of abundance. The literature on abalone fisheries suggests that this assumption is questionable and that CPUE is difficult to use in abalone stock assessments due to the serial depletion behaviour of fishers along with the aggregating behaviour of abalone. Serial depletion is when fishers consecutively fish-down beds of paua but maintain their catch rates by moving to new unfished beds, thus CPUE stays high while the overall population biomass is actually decreasing. The aggregating behaviour of paua results in the timely re-colonisation of areas that have been fished down, as the cryptic paua, that were unavailable at the first fishing event, move to and aggregate within the recently depleted area. Both serial depletion and aggregation behaviour cause CPUE to have a hyperstable relationship with abundance (i.e. abundance is decreasing at a faster rate than CPUE) thus making CPUE a poor proxy for abundance. How strong an effect serial depletion and aggregation behaviour have on the relationship between CPUE and abundance in PAU 5D, is difficult to determine. However, because fishing has been consistent in PAU 5D for a number of years and effort has been reasonably well spread, it could be assumed that CPUE, in more recent years, is not as strongly influenced by these factors, relative to the early CPUE series.

The assumption of CPUE being a reliable index of abundance in PAU 5D can also be upset by exploitation of spatially segregated populations of differing productivity. This can cause non-linearity in the CPUE-abundance relationship, making it difficult to track changes in abundance by using changes in CPUE as a proxy.

For PAU 5D, there is also some additional uncertainty associated with the early CPUE series: the standardisations suggested that there were different trends among statistical areas (the overall indices were unlikely to track abundance as the weights for each area cannot be easily determined); the level of decline in the CPUE indices appeared too small for the early stage of the fishery.

A major source of uncertainty in the model is the low confidence around the estimate of natural mortality. The current basis for the assumption of natural mortality is somewhat *ad hoc*, and the prior used is considered to be unduly informative (Butterworth et al 2015). Although sensitivities were run with different *a priori* assumptions of M, it was clear that the estimates were highly influenced by this assumption suggesting the data are not very informative for making strong statements about the status of the stocks and also suggesting that a better understanding of this parameter/dynamic would likely reduce a large component of uncertainty in this assessment.

Another source of uncertainty is the data. The commercial catch is unknown before 1974 and is estimated with uncertainty before 1995. Major differences may exist between the catches we assume and what was actually taken. In addition, non-commercial catch estimates, including illegal catch, are poorly determined and could be substantially different from what was assumed.

Tag-recapture data were mainly from the Catlin areas and therefore may not reflect fully the average growth in the whole of the PAU 5D population. Model estimates of stock status were sensitive to the range of possible growth values examined. Maturity data were collected from Catlin West and may not represent the entire population either. Length frequency data collected from the commercial catch may not represent the commercial catch with high precision. The research diver survey covered only the Catlin Area, the abundance indices and associated length frequencies were unlikely to represent the trend in the whole population.

The model treats the whole of the assessed area of PAU 5D as if it were a single stock with homogeneous biology, habitat and fishing pressures. The model assumes homogeneity in recruitment and natural mortality, and assumes that growth has the same mean and variance throughout. However it is known that paua in some areas have stunted growth, and others are fast-growing.

Heterogeneity in growth can be a problem for this kind of model (Punt 2003). Variation in growth is addressed to some extent by having a stochastic growth transition matrix based on increments

observed in several different places; similarly the length frequency data are integrated across samples from many places.

The effect of these factors is likely to make model results optimistic. For instance, if some local stocks are fished very hard and others not fished, recruitment failure can result because of the depletion of spawners, because spawners must breed close to each other, and the dispersal of larvae is unknown and may be limited. Recruitment failure is a common observation in overseas abalone fisheries, so local processes may decrease recruitment, an effect that the current model cannot account for.

Another source of uncertainty is that fishing may cause spatial contraction of populations (Shepherd & Partington 1995), or that some populations become relatively unproductive after initial fishing (Gorfine & Dixon 2000). If this happens, the model will overestimate productivity in the population as a whole. Past recruitments estimated by the model might instead have been the result of serial depletion.

5. STATUS OF THE STOCK

Stock Structure Assumptions

PAU 5D is assumed in the model to be a discrete and homogenous stock

- **PAU 5D - *Haliotis iris***

Stock Status	
Year of Most Recent Assessment	2017
Assessment Runs Presented	Reference case MCMC
Reference Points	Interim Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	B_{2016} was estimated to be 35% B_0 . The stock is Unlikely (< 40%) to be at or above the target.
Status in relation to Limits	Unlikely (< 40%) to be below the soft limit and Very Unlikely (< 10%) to be below the hard limit.
Status in Relation to Overfishing	Overfishing is About as Likely as Not (40–60%) to be occurring

Historical Stock Status Trajectory and Current Status

Trajectory of exploitation rate as a ratio of U_{40B0} and spawning stock biomass as a ratio of B_0 from the start of assessment period 1965 to 2016 for MCMC model run 0.0. The vertical lines at 10%, 20%, 40% B_0 represent the hard limit, the soft limit, and the target respectively. U_{40B0} is the exploitation rate at which the spawning stock biomass would stabilise at 40% B_0 over the long term. Each point on the trajectory represents the estimated annual stock status: the value on the x axis is the mid-season spawning stock biomass (as a ratio of B_0) and the value on the y axis is the corresponding exploitation rate (as a ratio U_{40B0}) for that year. The trajectory started in year 1965 when the SSB was close to B_0 and the exploitation rate was close to 0. The estimates are based on MCMC medians and the 2016 90% CI is shown by the cross line.

Fishery and Stock Trends

Recent Trend in Biomass or Proxy	Biomass decreased from 1965 to 2002 and has since been relatively stable.
Recent Trend in Fishing Mortality or Proxy	Exploitation rate peaked in 2002 and has since declined.
Other Abundance Indices	Standardised CPUE generally declined until the early 2000s, but has shown a gradual increase since.
Trends in Other Relevant Indicators or Variables	Estimated recruitment between 2002 and 2009 has decreased below the long term average and since then has been increasing to close to the long term average.

Projections and Prognosis

Stock Projections or Prognosis	At the current catch level biomass is expected to increase over the next 3 years.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Results from all model assessment runs presented suggest it is Very Unlikely (< 10%) and Unlikely (< 40%) that current levels of catch or catch at the TACC, respectively, will cause a decline below the soft or hard limits.

Assessment Methodology and Evaluation

Assessment Type	1- Full Quantitative Stock Assessment
Assessment Method	Length based Bayesian model

Assessment Dates	Latest: 2017	Next: 2020
Overall assessment quality (rank)	1 – High Quality	
Main data inputs (rank)	<ul style="list-style-type: none"> - Catch History - CPUE Indices early series - CPUE Indices later series - Commercial sampling length frequencies - Tag recapture data - Maturity at length data 	<p>2 – Medium or Mixed Quality: not believed to be fully representative of catch in the QMA</p> <p>2 – Medium or Mixed Quality: not believed to be fully representative of CPUE in the QMA</p> <p>1 – High Quality</p> <p>2 – Medium or Mixed Quality: not believed to be representative of the whole QMA</p> <p>2 – Medium or Mixed Quality: not believed to be representative of the whole QMA</p> <p>2 – Medium or Mixed Quality: not believed to be representative of the whole QMA</p>
Data not used (rank)	<ul style="list-style-type: none"> - Research Dive survey indices - Research Dive length frequencies 	<p>3 – Low Quality: not believed to be a reliable indicator of abundance in the whole QMA</p> <p>3 – Low Quality: not believed to be a reliable indicator of length frequency in the whole QMA</p>
Changes to Model Structure and Assumptions	<ul style="list-style-type: none"> - Added a more flexible functional form to describe the variance associated with the mean growth increment at length - Mid-season abundance (and biomass) was calculated after half of the natural mortality and half of the fishing mortality was applied - Changed likelihood function for fitting the tag-recapture observations so that weights can be assigned to individual observations. 	
Major Sources of Uncertainty	<ul style="list-style-type: none"> - Growth data were limited and may not be representative of growth within the whole QMA. This was explored through models with alternative growth assumptions, which show the high degree of uncertainty about current stock status associated with uncertainty about growth. - Assuming CPUE is a reliable index of abundance. - The model treats the whole of the assessed area of PAU 5D as if it were a single stock with homogeneous biology, habitat and fishing pressures. - Any effect of voluntary increases in MHS from 125 mm to 132 mm over the last five years may not have been adequately captured by the model, which could therefore be underestimating the spawning biomass in recent years. - A major source of uncertainty in the model is the low confidence around the estimate of natural mortality. The current basis for the assumption of natural mortality is somewhat <i>ad hoc</i>, and the prior used is considered to be unduly informative (Butterworth et al 2015). Although sensitivities were run with different <i>a priori</i> assumptions of M, it was clear that the estimates were highly influenced by this assumption suggesting the data are not very informative for making strong statements about the status of the stocks and also suggesting that a better understanding of this parameter/dynamic would likely reduce a large component of 	

	uncertainty in this assessment.
Qualifying Comments	
The uncertainty in the reliability of CPUE as a proxy for abundance and the uncertainty in estimates of M, require caution when deciding which level of probability best reflects the status of the fishery.

PAUA (PAU 7) – Marlborough*(Haliotis iris)*

Pāua

**1. FISHERY SUMMARY**

PAU 7 was introduced into the Quota Management System in 1986–87 with a TACC of 250 t. As a result of appeals to the Quota Appeal Authority the TACC increased to 267.48 t by 1989. On 1st October 2001 a TAC of 273.73 t was set with a TACC of 240.73 t, customary and recreational allowances of 15 t each and an allowance of 3 t for other mortality. On 1 October 2002 the TAC was reduced to 220.24 t and the TACC was set at 187.24 t. No changes were made to the customary, recreational or other mortality allowances (Table 1).

Table 1: Total allowable catches (TAC, t) allowances for customary fishing, recreational fishing, and other sources of mortality (t) and Total Allowable Commercial Catches (TACC, t) declared for PAU 7 since introduction into the QMS.

Year	TAC	Customary	Recreational	Other mortality	TACC
1986–89	-	-	-	-	250.00
1989–2001					267.48
2001–02	273.73	15	15	3	240.73
2002–present	220.24	15	15	3	187.24

1.1 Commercial fisheries

The fishing year runs from 1 October to 30 September. In 2001–02 concerns about the status of the PAU 7 fishery led to a decision by the commercial sector to voluntarily shelve 20% of the TACC for that fishing year. From the 2003–04 to the 2006–07 fishing years the industry proposed to shelve 15% of the TACC. In the 2012–13 and 2012–13, the industry shelved 20% of the 187.24 t TACC. In 2014–15, PAU 7 stakeholders again agreed to voluntarily shelve 30%. However some only shelved 20% and some shelved 30%, and an average of 28% was shelved overall.

On 1 October 2001 it became mandatory to report catch and effort on PCELRs using fine-scale reporting areas (Figure 1) that had been developed by the New Zealand Paua Management Company for their voluntary logbook programme. Reported landings and TACCs for PAU 7 are shown in Table 2 and Figure 2.

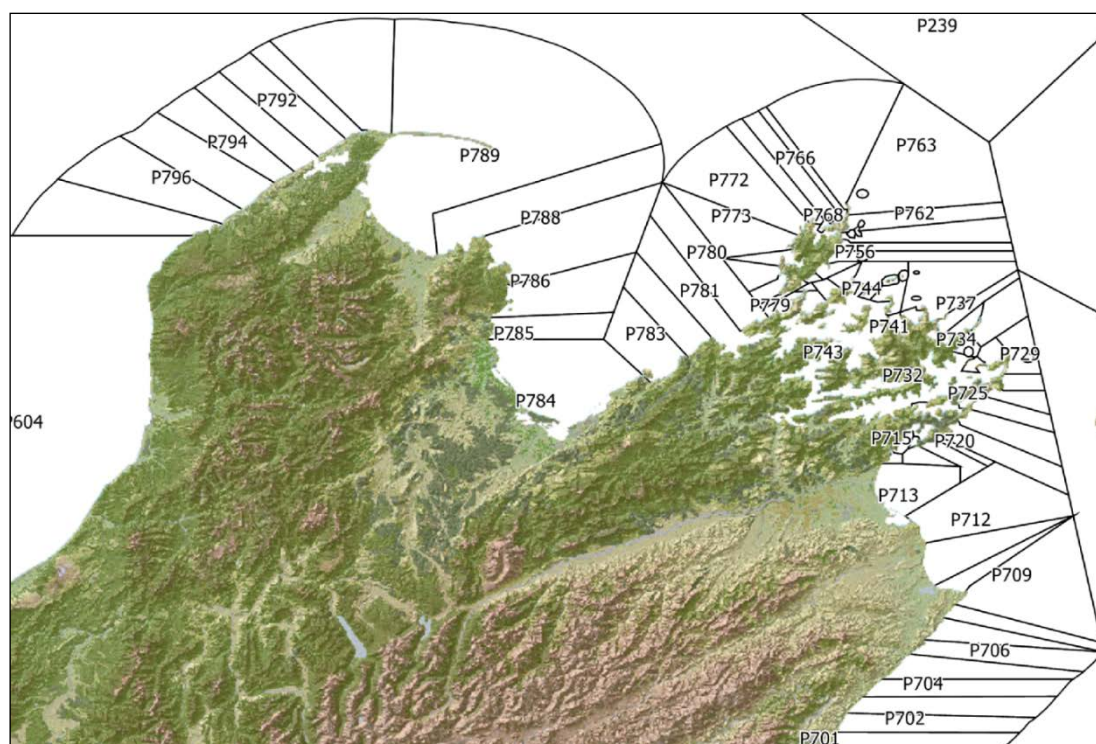

Figure 1: Map of fine scale statistical reporting areas for PAU 7.

Table 2: Reported Landings and TACC in PAU 7 from 1983–84 to the present. The last column shows the TACC after shelving has been accounted for.

Year	Landings (kg)	TACC (t)	Shelving	Year	Landings (kg)	TACC (t)	Shelving
1974–75	197 910	-	-	1995–96	268 742	267.48	267.48
1975–76	141 880	-	-	1996–97	267 594	267.48	267.48

* Voluntary shelving

1.2 Recreational fisheries

A nationwide panel survey of over 7000 marine fishers who reported their fishing activity over the fishing year from 1 October 2011 to 30 September 2012 was conducted by The National Research Bureau Ltd in close consultation with Marine Amateur Fishing Working Group (Wynne-Jones et al 2014). The survey is based on an improved survey method developed to address issues and to reduce bias encountered in past surveys. The survey estimated that about 50 534 paua, or 14.13 t (CV of 34%) were harvested by recreational fishers in PAU 7 for 2011–12. For this assessment, the SFWG agreed to assume that recreational catch was 5 t in 1974 and that it increased linearly to 15 t in 2000 and then remained at 15 t subsequently. For further information on recreational fisheries refer to the introductory PAU Working Group Report.

Figure 2: Reported commercial landings and TACC for PAU 7 from 1986–87 to present.

1.3 Customary fisheries

Customary catch was incorporated into the PAU 7 TAC in 2002 as an allowance of 15 t. There are no published estimates of customary catch. Records of customary catch taken under the South Island Regulations show that about 200 to 5500 paua were reported to have been collected each year from 2001–02 to 2014–15, with an average of 1700 pieces each year (or 0.68 t). Those numbers were substantially lower than the annual allowances. About 70% of the reported customary catch was taken from Port Underwood, Queen Charlotte Sound, and Tory Channel. The Working Group agreed to assume that customary catch was 4 t in 1974, increasing linearly to 5 t between 1974 and 2000 and then remaining at 5 t subsequently. For further information on customary fisheries refer to the introductory PAU Plenary chapter.

1.4 Illegal catch

There are no estimates of illegal catch for PAU 7. The Working Group agreed to assume that illegal catch was 1 t in 1974 and that it increased linearly to 15 t between 1974 and 2000, remaining at 15 t from 2000 to 2005, then decreasing linearly to 7.5 t in 2008, and then remaining at 7.5 t subsequently. For further information on illegal catch refer to the introductory PAU Plenary chapter.

1.5 Other sources of mortality

The Working Group agreed that handling mortality would not be factored into the model. For further information on other sources of mortality refer to the introductory PAU Plenary chapter.

On November 16th 2016 a 7.8 magnitude earthquake hit the upper east coast of the South Island, uplifting areas of the coast by as much as 4 m. In the PAU 7 fishery, paua statistical areas P701 to P710 were impacted to varying degrees by the earthquake. The earthquake caused direct mortality of a large number of juvenile and adult paua that became exposed to the terrestrial environment with no means of being able to return to the water. More indirect mortality is also expected from the earthquake due to an immediate loss of pre-earthquake paua habitat that now lies above the new post-earthquake high tide mark.

Impacts of the seabed uplift on paua populations in PAU 7 will only become clear in the longer term. The immediate loss of area to the fishery, assumed to be good habitat for paua, is only part of the impact that the seabed uplift associated with the earthquake will have on paua populations. Juvenile paua recruit in shallow water, and so the loss of juvenile habitat will have been higher than the loss of adult habitat. This will impact on the number of juvenile paua growing into the fishery over the coming years. This impact will be difficult to quantify directly, but may affect paua populations and fisheries over a span of multiple years.

2. BIOLOGY

For further information on pua biology refer to the introductory PAU Plenary chapter. A summary of biological parameters used in the PAU 7 stock assessment is presented in Table 3.

Table 3: Estimates of biological parameters (*H. iris*).

Fishstock		Estimate	Source
1. Natural mortality (<i>M</i>)			
All		0.02–0.25	Sainsbury (1982)
PAU 7	0.11 (0.10–0.13)	Median (5%–95% CI)	estimated from the base case assessment model
2. Weight = $a(\text{length})^b$ (weight in g, shell length in mm)			
	$a = 2.59\text{E-}08$	$b = 3.322$	Schiel & Breen (1991)
3. Size at maturity (shell length)			
50% mature	92 (91.3–92.7) mm	Median (5%–95% CI)	estimated by the assessment model
length at 95% mature - 50% mature	8.7 (9.6–13.4) mm	Median (5%–95% CI)	estimated by the assessment model
4. Exponential growth parameters (both sexes combined)			
l_{50}^g	104 (98.5–107.1) mm	Median (5%–95% CI)	estimated by the assessment model: length of animal at 50% maximum growth increment
l_{95-50}^g	30.9 (25.9–37.4) mm	Median (5%–95% CI)	estimated by the model: length of animal between at 50% and 95% maximum growth increment.
Δ_{\max}	30 (26.3–36.1) mm	Median (5%–95% CI)	estimated by the model: maximum growth increment

3. STOCKS AND AREAS

For further information on stocks and areas refer to the introductory PAU Plenary chapter.

4. STOCK ASSESSMENT

The stock assessment is implemented as a length-based Bayesian estimation model, with point estimates of parameters based on the mode of the joint posterior distribution, and uncertainty of model estimates investigated using the marginal posterior distributions generated from Markov chain-Monte Carlo simulations. The 2015 assessment was restricted to Statistical Areas 017 and 038, which includes approximately 85–95% of the catch over the past 10 years.

4.1 Estimates of fishery parameters and abundance indices

Parameters estimated in the assessment model and their assumed Bayesian priors are summarised in Table 4.

4.1.1 Relative abundance estimates from standardised CPUE analyses

The 2015 stock assessment used two sets of standardised CPUE indices: one based on CELR data covering 1990–2001, and another based on PCELR data covering 2002–2015. For both series, standardised CPUE analyses were carried out using Generalised Linear Models (GLMs). A stepwise procedure was used to select predictor variables, with variables entering the model in the order that gave the maximum decrease in the residual deviance. Predictor variables were accepted in the model only if they explained at least 1% of the deviance.

Table 4: A summary of estimated model parameters, lower bound, upper bound, type of prior, (*U*, uniform; *N*, normal; *LN* = lognormal), mean and CV of the prior.

Parameter	Definition	Phase	Prior	μ	CV	Lower	Upper
$\ln(R0)$	Natural log of base recruitment	1	U	–	–	5	50
M	Instantaneous rate of natural mortality	3	LN	0.1	0.1	0.01	0.5
Δ_{max}	Maximum growth increment	2	U	–	–	1	50
l_{50}^g	length at 50% maximum growth	2	U	–	–	0.01	150
l_{95-50}^g	length between 50% and 95% maximum growth	2	U	–	–	0.01	150
α	parameter that defines the variance of growth increment	2	U	–	–	0.001	5
β	parameter that defines the variance of growth increment		U	–	–	0.001	5
$\ln(q')$	Catchability coefficient of CPUE	1	U	–	–	-30	0
$\ln(q'')$	Catchability coefficient of PCPUE	1	U	–	–	-30	0
L_{50}	Length at which maturity is 50%	1	U	–	–	70	145
L_{95-50}	Interval between L_{50} and L_{95}	1	U	–	–	1	50
T_{50}	Length at which Fighting Bay length frequency selectivity is 50%	2	U	–	–	70	125
T_{95-50}	Difference between T_{50} and T_{95}	2	U	–	–	0.001	50
D_{50}	Length at which commercial diver selectivity is 50%	2	U	–	–	70	145
D_{95-50}	Difference between D_{50} and D_{95}	2	U	–	–	0.01	50
ϵ	Vector of annual recruitment deviations from 1977 to 2013	1	N	0	0.4	-2.3	2.3
D_s	Change in commercial diver selectivity for one unit of change of MHS	1	U	–	–	0.01	10

The observational data were:

1. A standardised CPUE series covering 1983–2001 based on FSU/CELR data.
2. A standardised CPUE series covering 2002–2015 based on PCELR data.
3. A length frequency dataset from the Fighting Bay fish-down experiment (FBLF).
4. A commercial catch sampling length frequency series (CSLF).
5. Tag-recapture length increment data.
6. Maturity at length data

For both the CELR and PCELR data, the Fisher Identification Number (FIN) was used in the standardisations instead of vessel, because the FIN is associated with a permit holder who may employ a suite of grouped vessels, which implies that there could be linkage in the catch rates among vessels operated under a single FIN. FIN codes were used to select a core group of fishers from the CELR data, with the requirement to qualify for the core fisher group that there be a minimum of 15 records per year for a minimum of 3 years. For the PCELR data the FIN was also used to select a core group of fishers, with the requirement that there be a minimum of 20 records per year for a minimum of 8 years. For both periods, over 80% of catches were retained.

For the CELR data there is ambiguity in what is recorded for estimated daily fishing duration: either incorrectly recorded as hours *per diver*, or correctly as total hours *for all* divers. For PAU 7, fishing duration appeared to have been predominantly recorded as hours per diver. The standardisation was therefore restricted to records where fishing duration ≤ 10 hours. This subset of data was used for the CELR standardisation using estimated daily catch, and effort as fishing duration.

For the PCELR data the unit of catch was diver catch, with effort as diver duration.

For the CELR data, year was forced into the model and other predictor variables offered to the model were FIN and fishing duration (as a cubic polynomial). For the PCELR data, fishing year was forced into the model and variables offered to the model were month, diver key, FIN statistical area, diver duration (third degree polynomial), and diving conditions.

PAUA (PAU 7)

The standardised CELR index shows a decline from the early 1990s to 2001. The standardised PCELR index shows an increase from 2002 to 2008 with an overall slow decline since then (Figure 3).

Figure 3: The standardised CPUE indices with 95% confidence intervals for the early CELR series (left) and the recent PCELR series (right).

4.1.2 Relative abundance estimates from research diver surveys

The relative abundance of paua in PAU 7 was also estimated from a number of independent research diver surveys (RDSI) undertaken in various years between 1992 and 2005. Concerns about the reliability of these data to estimate relative abundance instigated reviews in 2009 (Cordue 2009) and 2010 (Haist 2010). The reviews assessed i) the reliability of the research diver survey index as a proxy for abundance and ii) whether the RDSI, when used in the paua stock assessment models, results in model outputs that adequately reflect the status of the stocks. Both reviews suggested that outputs from paua stock assessments using the RDSI should be treated with caution. For a summary of the conclusions from the reviews refer to the introductory PAU Plenary chapter.

4.2 Stock assessment methods

The 2015 PAU 7 stock assessment used the length-based model first used in 1999 for PAU 5B (Breen et al 2000) and revised for subsequent assessments in PAU 7 (Breen et al 2001, Breen & Kim 2003, 2005, McKenzie & Smith 2009b, Fu 2012). The model was described in Breen et al (2003). The assessment also addressed a number of recommendations made by the paua review workshop held in Wellington in March 2015 (Butterworth et al 2015)

The model structure assumes a single sex population residing in a single homogeneous area, with length classes from 70 mm to 170 mm, in groups of 2 mm. Growth is length-based, without reference to age, mediated through a growth transition matrix that describes the probability of each length class changing at each time step. Paua enter the partition following recruitment and are removed by natural mortality and fishing mortality. The assessment addresses only Areas 017 and 038 within PAU 7. These areas have supported over 90% of the catch until recently, and all of the available data originate from these two areas, but the relationship between this subset of PAU 7 and the remainder of PAU 7 is uncertain.

The model simulates the population dynamics from 1965 to 2015. Catches were available for 1974–2015, and were assumed to increase linearly between 1965 and 1973 from 0 to the 1974 catch level. Catches included commercial, recreational, customary, and illegal catch, and all catches occurred within the same time step.

Recruitment was assumed to take place at the beginning of the annual cycle, and length at recruitment was defined by a uniform distribution with a range between 70 and 80 mm. The stock-recruitment relationship is unknown for paua. A relationship may exist on small scales, but not be apparent when large-scale data are modelled (Breen et al 2003). No explicit stock-recruitment relationship was modelled in previous assessments; however, the SFWG agreed to use a Beverton-Holt stock-recruitment relationship with steepness (h) of 0.75 for this assessment.

Maturity is not required in the population partition. The model estimated proportions mature with the inclusion of length-at-maturity data. Growth and natural mortalities were also estimated within the model.

The models used two selectivities: the commercial fishing selectivity and the Fighting Bay catch sample selectivity, both assumed to follow a logistic curve and to reach an asymptote.

The assessment was conducted in several steps. First, the model was fitted to the data with arbitrary weights on the various data sets. The weights were then iteratively adjusted to produce balanced residuals among the datasets where the standardised deviation of the normalised residuals was close to one for each dataset. The fit obtained is the mode of the joint posterior distribution of parameters (MPD). Next, from the resulting fit, Markov chain-Monte Carlo (MCMC) simulations were made to obtain a large set of samples from the joint posterior distribution. From this set of samples, forward projections were made with a set of agreed indicators obtained. Sensitivity trials were explored by comparing MPD fits made with alternative model assumptions.

A base case model (1.0) was chosen by the Shellfish Working Group for the assessment: The base case model is configured such that (a) predicted CPUE is calculated after half of the natural and fishing mortality has occurred; (b) Francis (2011) method was used to determine the weight of CSLF and CPUE; (c) growth was estimated using the inverse-logistic model; (d) tag-recapture observations from the Staircase were excluded; (e) tag-recapture observations were weighted by the catch in each area; (f) the CPUE shape parameter was fixed at 1 assuming a linear relationship between CPUE and abundance. The base case used a lognormal prior on M , with $\mu_M = 0.1$ and $\sigma_M = 0.1$. The choice of CV was arbitrary, but generally chosen to be very informative to prevent obtaining unrealistic estimates. A sensitivity run (MCMC 1.4) used a prior ($\mu_M = 0.15$ and $\sigma_M = 0.25$) developed from posterior estimates of M from assessments of PAU 5A and PAU 5B, based on the recommendation from the paau review workshop (Butterworth et al 2015).

The SFWG also suggested the following sensitivity runs: using a smaller CV of 0.05 (model 1.1), or a larger CV of 0.12 (1.2); estimating the CPUE shape parameter assuming a uniform prior bounded between 0.5 and 1.5 (1.3), or fixing it at the lower (1.3a) and upper value (1.3b) respectively; using an alternative prior when estimating natural mortality; including tag-recapture observations from the Staircase (1.5). The base case and sensitivities are summarised in Table 5.

The assessment calculates the following quantities from their posterior distributions: the equilibrium spawning stock biomass assuming that recruitment is equal to the average recruitment from the period for which recruitment deviation were estimated (B_0), the mid-season spawning and recruited biomass for 2015 (B_{2015} and B_{2015}^r) and for the projection period (B_{proj} and B_{proj}^r). This assessment also reports the following fishery indicators:

$B\% B_0$	Current or projected spawning biomass as a percentage of B_0
$B\% B_{msy}$	Current or projected spawning biomass as a percentage of B_{msy}
$\Pr(B_{proj} > B_{msy})$	Probability that projected spawning biomass is greater than B_{msy}
$\Pr(B_{proj} > B_{2015})$	Probability that projected spawning biomass is greater than $B_{current}$
$B\% B_0^r$	Current or projected recruited biomass as a percentage of B_0^r
$B\% B_{msy}^r$	Current or projected recruited biomass as a percentage of B_{msy}^r
$\Pr(B_{proj}^r > B_{msy}^r)$	Probability that projected recruit-sized biomass is greater than B_{msy}^r
$\Pr(B_{proj}^r > B_{2015}^r)$	Probability that projected recruit-sized biomass is greater than B_{2015}^r
$\Pr(B_{proj} > 40\% B_0)$	Probability that projected spawning biomass is greater than 40% B_0
$\Pr(B_{proj} < 20\% B_0)$	Probability that projected spawning biomass is less than 20% B_0
$\Pr(B_{proj} < 10\% B_0)$	Probability that projected spawning biomass is less than 10% B_0
$\Pr(U_{proj} > U_{40\% B_0})$	Probability that projected exploitation rate is greater than $U_{40\% B_0}$

Forward projections (2016–2018) were made for the base case with a number of alternative future catch scenarios. Future recruitment deviations were resampled from model estimates either from 2002–2011 (a period with both high and low recruitment), or from 2010–2011 (a period with low recruitment). The total catch used in the projections was 142 717 kg (28% TACC reduction), 131 515 (35% TACC reduction), 123 514 kg (40% shelving), 107 511 kg (50% shelving) and 91 510 kg (60% TACC), and 27 500 kg (100% TACC reduction).

Table 5: Summary descriptions of base case and sensitivity model runs.

Model	Description
1.0	base case, Francis (2011) weighting, inverse logistic, excluded Staircase growth, growth data weighted
1.1	1.0, CV for CPUE2 = 0.5
1.2	1.0, CV for CPUE2 = 1.2
1.3	1.0, estimated CPUE shape parameter with a uniform prior [0.5,1.5]
1.3a	1.0, CPUE shape parameter = 0.5
1.3b	1.0, CPUE shape parameter = 1.5
1.4	1.0, M estimated with a prior developed using information from PAU 5A and PAU 5B.
1.5	1.0, included Staircase growth

4.2.1 Stock assessment results

Current estimates from the base case suggested that spawning stock population in 2015 ($B_{current}$) was about 18% (16–21%) of the unfished level (B_0), or 69% (16–21%) of B_{msy} (Figure 4, Table 6). Estimated recent recruitment has been below average (recruitment in 2010 and 2011 was the lowest after 2002). The estimated exploitation rate has declined since 2003, and was further reduced after 2012. The exploitation rate in 2015 was estimated to be 0.46 (0.40–0.52).

The model projection made for three years using recruitment re-sampled from a period with both high and low recruitment (2002–2011), suggested that the spawning stock abundance will increase to 22% (16–29%) of B_0 in 2018 if the future catch remains at the current level (corresponding to a 28% TACC shelving), or 24% (18–31%) of B_0 if the future catch is reduced to 50% of the TACC (Figure 5). The projections using recruitment re-sampled from the recent period with low recruitment (2010–2011), suggested that the spawning stock abundance will only increase to 19% (14–25%) of B_0 in 2018 if the future catch remains at the current level, or 21% (16–27%) of B_0 with a 50% TACC reduction (Figure 6). It was extremely unlikely that the stock status will be above the target (40% B_0) in the short term.

The base case model matched very closely with the early CPUE and predicted CPUE indices were all well within the confidence bounds of the observed values. Predicted CPUE declined more than observed values between 2009 and 2013. However, the overall change in relative abundance between 2002 and 2015 is similar between the predicted and observed values. The standardised residuals show no apparent departure from the model's assumption of normality. Commercial catch length frequencies were well fitted for most years. The mean length of CSLF has increased since 2003, and has remained reasonably stable since 2007, except in 2014. The average fish size in the catch in recent years has been well below those in the early 1990s. The standardised residuals of the fits to CSLF revealed that in general the model predicted a slightly narrower distribution than what was observed in the catch. This might be because the fishery has been fished down to a low level and the chance of sampling paua of large sizes has reduced. Estimated logistic selectivity was very close to knife-edge around the MLS, with a small increase in 2015. Fits to growth increment and maturity data appeared adequate. The relative weight assigned to tag-recapture observations from Perano and Rununder was about three times more than those from Northern Faces, and as a result, estimated mean growth was higher than if equal weights were assumed. The Fighting Bay length frequency fitted well, suggesting this length distribution was consistent with the estimated growth rates in the model.

Table 6: Summary of the marginal posterior distributions from the MCMC chain from the base case (1.0) and sensitivities. The columns show the medians and the 5th and 95th percentiles. Biomass is in tonnes.

Changes in stock size in response to fishing pressure over time are shown in Figure 7. This was done by plotting the annual spawning biomass and exploitation rate as a ratio of a reference value from 1965 to 2015. Each point on the trajectory represents the estimated annual stock status: the value on the x axis is the mid-season spawning stock biomass as a ratio of B_0 , the value on the y axis is the corresponding exploitation rate as a ratio of $U_{40\%B_0}$ for that year. The trajectory started in 1965 when the SSB is close to B_0 and the exploitation rate is close to 0. The model indicated an early phase of the fishery where the exploitation rates were below $U_{40\%B_0}$ and the SSBs were above 40% B_0 and a development phase where the exploitation rates increased and the SSBs decreased in relation to the target. The current exploitation rate is about twice of $U_{40\%B_0}$ and the current spawning stock biomass is just below 20% B_0 .

Figure 4: Posterior distribution of spawning stock biomass as a percentage of virgin level from MCMC 1.0. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Figure 5: Posterior distributions of projected spawning stock biomass 2016–2018 for the base case (MCMC 1.0) with future recruitment resampled from model estimates 2002–2011 under six catch scenarios: 28% TACC reduction (gray), 35% TACC reduction (black), 40% TACC reduction (orange), 50% TACC reduction (green), 60% TACC reduction (blue), and 100% TACC reduction shelving (red). The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Figure 6: Posterior distributions of projected spawning stock biomass 2016–2018 for the base case (MCMC 1.0) with future recruitment resampled from model estimates 2010–2011 under three catch scenarios: 28% TACC reduction (gray), 40% TACC reduction (red), 50% TACC reduction (green), 60%. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Figure 7: Trajectory of exploitation rate as a ratio of $U_{40\%B_0}$ and spawning stock biomass as a ratio of B_0 , from the start of assessment period 1965 to 2015 for MCMC 1.0 (base case). The vertical lines at 10%, 20% and 40% B_0 represent the soft limit, the hard limit, and the target. Estimates are based on MCMC median and the 2015 90% marginal CI is shown by the cross line, and joint CI is shown by the grey area.

4.3 Other factors

The stock assessment model assumed homogeneity in recruitment, and that natural mortality does not vary by size or year, and that growth has the same mean and variance throughout the entire area. However, it is known that paua fisheries are spatially variable and that apparent growth and maturity in paua populations can vary over very short distances. Variation in growth is addressed to some extent by having a stochastic growth transition matrix based on tagging data collected from a range of different

locations. Similarly, the length frequency data are integrated across samples from many places. The effect of this integration across local areas is likely to make model results optimistic.

For instance, if some local stocks are fished very hard and others not fished, local recruitment failure can result due to the limited dispersal range of this species. Recruitment failure is a common observation in overseas abalone fisheries. Fishing may also cause spatial contraction of populations (e.g., Shepherd & Partington 1995), and some populations appear to become relatively unproductive after initial fishing (Gorfine & Dixon 2000). If this happens, the assessment will overestimate productivity in the population as a whole. It is also possible that good recruitments estimated by the model might have been the result of serial depletion.

CPUE provides information on changes in relative abundance. However, CPUE is generally considered to be a poor index of stock abundance for paua, due to divers' ability to maintain catch rates by moving from area to area despite a decreasing biomass (hyperstability). Breen & Kim (2003) argued that standardised CPUE might be able to relate to the changes of abundance in a fully exploited fishery such as PAU 7, and a large decline in the CPUE is most likely to reflect a decline in the fishery. Analysis of CPUE currently relies on Paua Catch Effort Landing Return (PCELR) forms, which record daily fishing time and catch per diver on a relatively large spatial scale. These data will likely remain the basis for stock assessments and formal management in the medium term.

Since October 2010, a dive-logger data collection program has been initiated to achieve fine-scale monitoring of paua fisheries (Neubauer et al 2014, Neubauer & Abraham 2014). The use of the data loggers by paua divers and ACE holders has been steadily increasing over the last three years. Using fishing data logged at fine spatial and temporal scales can substantially improve effort calculations and the resulting CPUE indices and allow complex metrics such as spatial CPUE to be developed (Neubauer & Abraham 2014). Data from the loggers have been analysed to provide comprehensive descriptions of the spatial extent of the fisheries and insight on relationships between diver behavior, CPUE, and changes in abundance on various spatial and temporal scale (Neubauer et al 2014, Neubauer & Abraham 2014, Neubauer 2015). However the data-loggers can potentially change how the divers operate such that they may become more effective in their fishing operations (the divers become capable of avoiding areas that have been heavily fished or that have relatively low CPUE without them having to go there to discover this), therefore changing the meaning of diver CPUE (Butterworth 2015).

Commercial catch length frequencies provide information on changes in population structure under fishing pressure. However, if serial depletion has occurred and fishers have moved from area to area, samples from the commercial catch may not correctly represent the population of the entire stock. For PAU 7, there has been a long time-series of commercial catch sampling and the spatial coverage of the available samples is generally considered to be adequate throughout the years.

4.4 Future research needs

- Increased tagging to obtain better fine scale growth information
- Consider including more of the east coast in the assessment, noting that this would need to be considered as a separate fishery due to differences in size limits
- Examine the possibility of spatial patterns in length and growth.

5. STATUS OF THE STOCKS

Stock Structure Assumptions

The 2015 assessment was conducted for Statistical Areas 017 and 038 only, but these include most (more than 90%) of the recent catch.

- PAU 7- *Haliotis iris*

Stock Status	
Year of Most Recent Assessment	2015
Assessment Runs Presented	Base case MCMC
Reference Points	Interim Target: 40% B_0 Soft Limit: 20% B_0 Hard Limit: 10% B_0 Overfishing threshold: $U_{40\%B_0}$
Status in relation to Target	Spawning stock biomass was estimated to be 18% B_0 and is Very Unlikely (< 10%) to be at or above the target
Status in relation to Limits	Spawning stock biomass was estimated to be 18% B_0 , and is About as Likely as Not (40–60%) to be below the soft limit and Unlikely (< 40%) to be below the hard limit
Status in relation to Overfishing	In 2014–15 the fishing intensity was Very Likely (> 90%) to be above the overfishing threshold

Historical Stock Status Trajectory and Current Status

Posterior distribution of spawning stock biomass as a percentage of virgin level from MCMC 1.0. The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Posterior distributions of projected spawning stock biomass 2016–2018 for the base case (MCMC 1.0) with future recruitment resampled from model estimates 2002–2011 under six catch scenarios: 28% TACC reduction (gray), 35% TACC reduction (black), 40% TACC reduction (orange), 50% TACC reduction (green), 60% TACC reduction (blue), and 100% TACC reduction shelving (red). The box shows the median of the posterior distribution (horizontal bar), the 25th and 75th percentiles (box), with the whiskers representing the full range of the distribution.

Trajectory of exploitation rate as a ratio of $U_{40\%B_0}$ and spawning stock biomass as a ratio of B_0 , from the start of assessment period 1965 to 2015 for MCMC 1.0 (base case). The vertical lines at 10%, 20% and 40% B_0 represent the soft limit, the hard limit, and the target. Estimates are based on MCMC median and the 2015 90% marginal CI is shown by the cross line, and joint CI is shown by the grey area.

Fishery and Stock Trends	
Recent Trend in Biomass or Proxy	Biomass reached its lowest point in 2002–03. It has since fluctuated at or just below the soft limit.
Recent Trend in Fishing Intensity or Proxy	Fishing intensity peaked in 2003 but has subsequently declined.
Other Abundance Indices	-
Trends in Other Relevant Indicators or Variables	-

Projections and Prognosis	
Stock Projections or Prognosis	Three year projections indicate that spawning biomass will increase slightly, to varying degrees, under different levels of catch when future recruitment is resampled from 2002–2011 but it is Very Unlikely (< 10%) to be at or above the target by this time.
Probability of Current Catch or TACC causing Biomass to remain below or to decline below Limits	Soft Limit: About as Likely as Not (40–60%) Hard Limit: Unlikely (< 40%)
Probability of Current Catch or TACC causing Overfishing to continue or commence	Very Likely (> 90%)

Assessment Methodology & Evaluation		
Assessment Type	Full quantitative stock assessment	
Assessment Method	Length based Bayesian model	
Assessment Dates	Latest assessment: 2015	Next assessment: 2018

PILCHARD (PIL)*(Sardinops sagax)*

Mohimohi

**1. FISHERY SUMMARY**

Pilchards were introduced into the QMS in October 2002 with allowances, TACCs and TACs as shown in Table 1.

Table 1: Recreational and Customary non-commercial allowances, TACCs and TACs by Fishstock.

Fishstock	Recreational Allowance	Customary Non-commercial Allowance	TACC	TAC
PIL 1	20	10	2 000	2 030
PIL 2	10	5	200	215
PIL 3	5	2	60	67
PIL 4	3	2	10	15
PIL 7	10	5	150	165
PIL 8	10	5	65	80
PIL 10	0	0	0	0

1.1 Commercial fisheries

Pilchards occur around most of New Zealand, however, commercial fisheries have only developed in north-eastern waters (east Northland to Bay of Plenty), and in Tasman Bay and Marlborough Sounds at the north of the South Island.

Historical estimated and recent reported pilchard landings and TACCs are shown in Tables 2 and 4, while Figure 1 shows the historical and recent landings and TACC values for the main pilchard stocks.

The first recorded commercial landings of pilchards were in 1931 (Table 2), but a minor fishery existed before this. Informal sales, mainly as bait, or as food for zoos and public aquariums, were unreported. A fishery for pilchard developed in the Marlborough Sounds in 1939 and operated through the war years providing canned fish for the armed forces. Landings reached over 400 t in 1942, but the fishery was unsuccessful for a variety of reasons and ceased in 1950. Between 1950 and 1990 landings were generally less than 20 t, intermittently reaching 70–80 t.

From 1990–91 the northeastern fishery was developed by vessels using both lampara nets and purse seines (Table 3). Lampara netting was the main method in the first couple of years, and continued at a low level through the 1990s. From 1993–94 onwards, purse seining became the dominant method. A diminishing catch (less than 10 t annually) was caught by beach seine. Almost all the pilchard catch (particularly in the northeastern fishery) is targeted. A small catch (less than 10 t annually), has been recorded as a bycatch of jack mackerel targeting. Total annual landings increased steadily from 1990

PILCHARD (PIL)

as the fishery developed in northeastern waters, reaching over 1200 t in 1999–00, and almost 1500 t in 2000–01. Landings declined consistently after 2003–04, largely influenced by catches from PIL 1, and since 2010–11 have been between 221 and 391t. Landings in PIL 8 have fluctuated between 12 t and 153 t since this stock was introduced to the QMS. The sudden increase in catches in PIL 8 from 1999–2000 to 2005–06 was thought to be in part the result of previously unreported catches now being reported due to the species being introduced to the QMS.

Table 2: Reported landings (t) for the main QMAs from 1931 to 1990.

Notes:

1. The 1931–1943 years are April–March but from 1944 onwards are calendar years.
2. Data up to 1985 are from fishing returns: Data from 1986 to 1990 are from Quota Management Reports.
3. Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of under-reporting and discarding practices. Data includes both foreign and domestic landings.

Table 3: Reported total New Zealand landings (t) of pilchard from 1931 to 1990.

Year	Landings	Year	Landings	Year	Landings	Year	Landings	Year	Landings	Year	Landings

Source: Annual reports on fisheries and subsequent MAF data.

A 2000 t annual Commercial Catch Limit (CCL) was introduced for FMA 1 from 01 October 2000. The CCL was subject to a logbook programme, a catch spreading arrangement and the avoidance of areas of particular importance to non-commercial fishers. The CCL was superseded when the PIL 1 stock was introduced to the QMS with a TACC of 2000 t on 1st October 2002.

1.2 Recreational fisheries

Recreational fishers seldom target pilchards, except perhaps for bait. However bait is generally bought in commercially frozen packs (the main product of the commercial fishery). Pilchard may be caught accidentally in small mesh nets that are set or dragged to catch mullet, or on small hooks fished from wharves.

A National Panel Survey of recreational fishers was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year. The panel members were contacted regularly about their fishing activities and harvest information collected in

PILCHARD (PIL)

standardised phone interviews. Harvest estimates for pilchard (in number of fish) are given in Table 5 (from Wynne-Jones et al 2014).

Table 5: Recreational harvest estimates for pilchard stocks (Wynne-Jones et al 2014). Mean fish weights were not available from boat ramp surveys to convert these catches to tonnes.

Stock	Year	Method	Number of fish	Total weight (t)	CV
PIL 1	2011/12	Panel survey	12 827	-	0.47
PIL 2	2011/12	Panel survey	1 022	-	0.83
PIL 3	2011/12	Panel survey	9 144	-	0.99
PIL 7	2011/12	Panel survey	101	-	1.05
PIL 8	2011/12	Panel survey	137	-	1.01
PIL total	2011/12	Panel survey	23 231	-	0.47

A repeat of the National Panel Survey is being conducted over the 2017–18 October fishing year. Results are expected in early 2019.

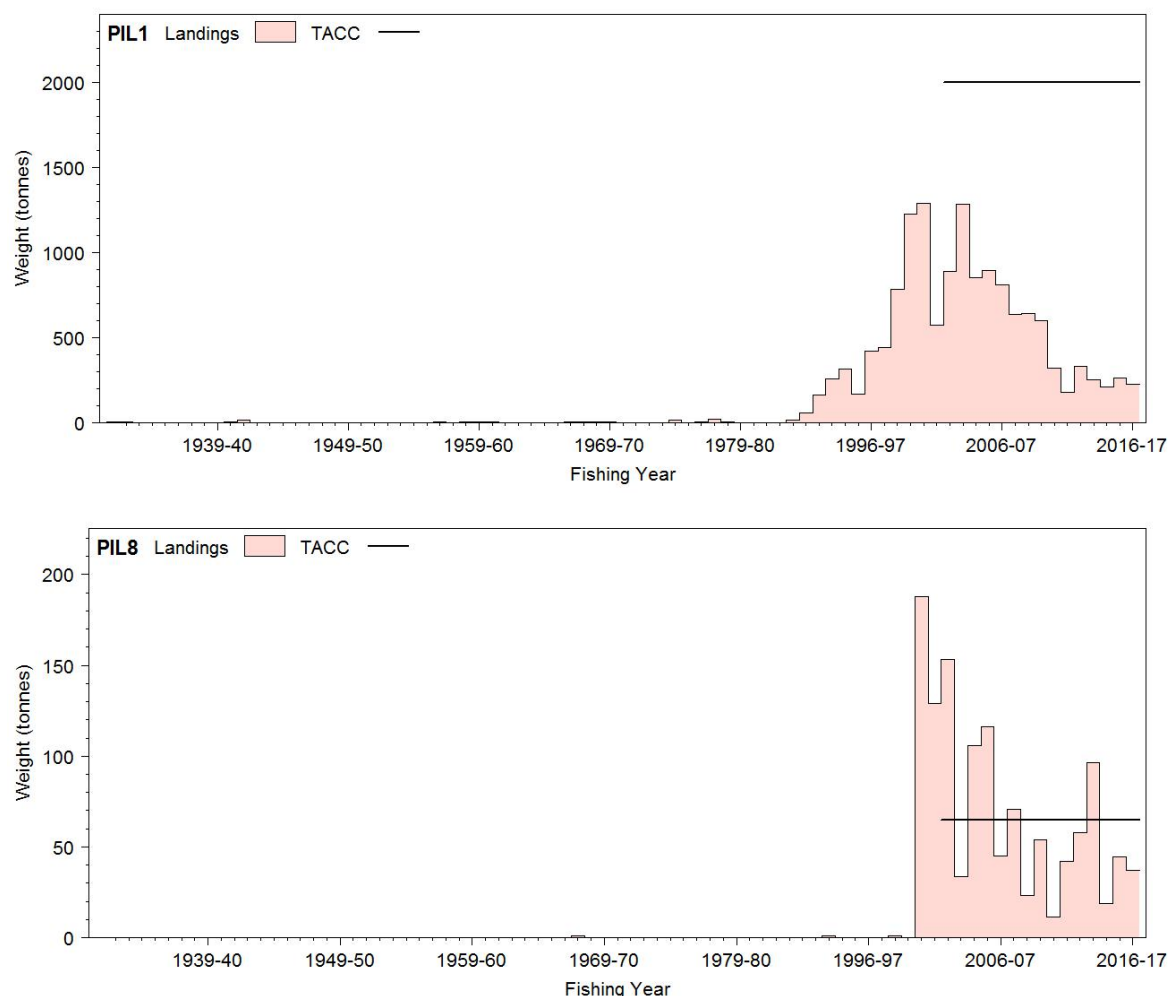

Figure 1: Reported commercial landings and TACC for the two main PIL stocks. PIL 1 (Auckland East), and PIL 8 (Central Egmont, Auckland West).

1.3 Customary non-commercial catch

Pilchards were known by the early Maori as mohimohi, and could have been taken in fine mesh nets, but there are very few accounts of pilchard capture and use. An estimate of the current customary non-commercial catch is not available.

1.4 Illegal catch

There is no known illegal catch of pilchards.

1.5 Other sources of mortality

Some accidental captures by vessels purse seining for jack mackerel or kahawai may be discarded if no market is available. Pilchard mortality is known to be high in some places as a result of scale loss resulting from net contact.

2. BIOLOGY

The taxonomy of *Sardinops* is complex. The New Zealand pilchard was previously identified as *Sardinops neopilchardus*, but there is now considered to be a single species, *S. sagax*, with several regional subspecies or populations.

Pilchard are generally found inshore, particularly in gulfs, bays, and harbours. They display seasonal changes in abundance (e.g. locally abundant in Wellington Harbour during spring), reflecting schooling and dispersal behaviour, localised movement, and actual changes in population size. The geographical extent of their movements in New Zealand is unknown.

Their vertical distribution in the water column varies, but on the inner shelf they move between the surface and the seafloor. Pilchards form compact schools (known as ‘meatballs’), particularly during summer, and these are heavily preyed upon by larger fishes, seabirds, and marine mammals and are thought to form an important part of the diet for many species. There have been no biological studies that are directly relevant to the recognition of separate stocks.

Spawning is recorded from many coastal regions over the shelf during spring and summer. The pelagic eggs are at times extremely abundant. Otolith readings suggest that pilchard are relatively fast growing and short-lived. They reach a maximum length of about 25 cm, and perhaps 9 years, but the main size range is of 10–20 cm fish, 2 to 6 years old. Maturity is probably at age 2.

A study on the feeding of Northland pilchards found that phytoplankton was probably the dominant food, but organic detritus was also important, and small zooplankton - mainly copepods - were taken and at times were the main component. Feeding by females diminished during the spawning season. Although they generally comprise single-species schools, pilchards associate with other small pelagic fishes, particularly anchovy. In northern waters they also occur with juvenile jack mackerel, and in southern waters with sprats.

During the 1990s pilchard populations were severely impacted by natural mass mortalities, generally attributed to a herpes virus. The first outbreak occurred in Australia and New Zealand in 1995 and Australia experienced another outbreak in 1998.

Biological parameters relevant to stock assessment are shown in Table 6.

3. STOCKS AND AREAS

No biological information is available on which to make an assessment on whether separate pilchard biological stocks exist in New Zealand (in Australia there is evidence of small differences between some populations off the southwest coast).

Pilchard and anchovy are often caught together. Pilchard fishstock boundaries are fully aligned with those for anchovy.

Table 6: Estimates of biological parameters.

Fishstock	Estimate		Source
<u>1. Natural mortality (<i>M</i>)</u>			
PIL 1	<i>M</i> = 0.66	NIWA, unpublished estimate ¹	
PIL 1	<i>M</i> = 0.46	NIWA, unpublished estimate ²	
<u>2. Weight = a (length)^b</u>			
	<u>Both sexes combined</u>		
PIL 1	a = 2.2	b = 3.3	Paul et al (2001) ³
PIL 7	a = 3.7	b = 3.3	Baker (1972) ⁴

Notes:

1. Hoenig's rule-of-thumb estimate, maximum age = 7 years.
2. Hoenig's rule-of-thumb estimate, maximum age = 10 years.
3. Fork length in mm, weight in g, $n = 493$.
4. Standard length in mm, weight in g, $n = 660$.

4. STOCK ASSESSMENT

There have been no stock assessments of New Zealand pilchard.

4.1 Estimates of fishery parameters and abundance

No fishery parameters are available.

4.2 Biomass estimates

No estimates of biomass are available.

4.3 Yield estimates and projections

(i) Northeast North Island (PIL 1)

MCY has been estimated using the equation $MCY = cY_{AV}$ (Method 4). The most appropriate Y_{AV} was considered the average of landings for the three years 1998–99 to 2000–01. Although a brief period, three years represents at least half the exploited life span for this species. The mean of these landings is 1101 t. With provisional values of M about 0.4 or 0.6, the value of c becomes 0.6 (i.e. high natural variability).

1998–99 to 2000–01

$$\begin{aligned}
 MCY &= 0.6 \times 1101 \text{ t} \\
 &= 661 \text{ t (rounded to 660 t)}
 \end{aligned}$$

However, the MCY approach is considered to be of limited value for pilchards, because this fishery has been developing rapidly, was historically infrequently targeted, and since 2000 has been subject to a CCL and more recently a TACC. The level of risk to the stock by harvesting the northeast North Island population at the estimated MCY value cannot be determined.

(ii) Tasman Bay/Marlborough Sounds (PIL 7)

MCY cannot be estimated for this region because the fishery has been largely unexploited since the 1940s, and no appropriate biological parameters exist.

(iii) Other regions

MCY cannot be estimated because of insufficient information, and absence of fisheries.

Current biomass cannot be estimated, so CAY cannot be determined.

4.4 Other factors

It is likely that pilchard, although not strongly migratory, will vary considerably in their regional abundance over time. The larger vessels in the fleet that targets them are capable of travelling moderate distances to the best grounds. Thus, while the resource may have a relatively localised distribution, the catching sector of the fishery does not. Should the pilchard fishery develop again

after its recent decline it is likely to become one component of a set of fisheries for small pelagic species (anchovy, sprats, and small jack mackerels). Mixed catches will be inevitable.

Pilchard is abundant in some New Zealand regions. However, it is unlikely that the biomass is comparable to the very large stocks of pilchard (sardine) in some world oceans where strong upwelling promotes high productivity. It is more likely that the New Zealand pilchard comprises abundant but localised coastal populations, comparable to those of southern Australia. They appear to be adaptable feeders, able to utilise food items from organic detritus through phytoplankton to zooplankton. East Northland is a region where under neutral to El Niño conditions moderately productive upwelling predominates but, in La Niña years, downwelling and oceanic water incursion will limit recruitment and may affect adult condition and survival.

In those regions of the world where small pelagic fishes are particularly abundant and have been well studied, there is often a reciprocal relationship between the stock size of pilchard and anchovy, as well as great variability in their overall abundance. Many pilchard/anchovy fisheries have undergone boom-and-bust cycles. In both Australia and New Zealand, pilchard have been affected by mass mortality events, the two in Australia are estimated to have each killed over 70% of the adult fish. The mortality rate of the 1995 event in New Zealand is not known, but was high. In combination, these features of the pilchard's biology suggest that the yield from the New Zealand stock will be variable, both short-term (annual) and long-term (decadal).

5. STATUS OF THE STOCKS

MCY estimates for PIL are unreliable. It is not known if the current catches or TACCs are sustainable.

Yield estimates, TACCs and reported landings by Fishstock are summarised in Table 7.

Table 7: Summary of yield estimates (t), TACCs (t), and reported landings (t) of pilchards for the most recent fishing year.

Fishstock		FMA	MCY Estimates	2016–17 Actual TACC	2016–17 Reported landings
PIL 1	Auckland (East)	1	660	2 000	226
PIL 2	Central (East)	2	–	200	0
PIL 3	South-east (Coast)/Southland & Sub-Antarctic	3, 5 & 6	–	60	0
PIL 4	South-east (Chatham)	4	–	10	0
PIL 7	Challenger	7	–	150	21
PIL 8	Central (West)/Auckland (West)	8, 9	–	65	37
PIL 10	Kermadec	10	–	0	0
